Wheat straw has been commonly made use of in laying up this sort of fruit; but Mr. Forsyth has found, that when any of the fruit begins to decay, if it be not quickly removed, the straw imbibes the moisture issuing from it, and communicates an unpleasant taste to such as is sound.

When fruit is stored up on shelves in the rooms, they are advised to have the bottoms covered with thin coarse canvass, at about eight-pence or ten-pence the yard, being placed upon it in single layers, after being wiped quite dry, care being taken not to lay them upon each other. They should then be covered with a piece of the same canvass, old news, or whited brown paper, to exclude the action of the air, guard against frost, and preserve the smoothness on the skin of the fruit. It should be turned two or three times in the course of the winter, to guard against rotting on the under side, all the damaged fruit being carefully removed each time.

In storing it in this manner, the earliest sorts should be placed on the lower shelves or drawers according as they come in, in this order; the nonsuch, golden rennet, and jenneting apples, and the burgainot and burre pears, as the jargonelle is found to keep best on the tree, rotting almost immediately on being gathered. In this way a proper succession of fruit may be provided.

As it requires much time in storing in this way where there is much fruit, it may be done in wet weather, and the evenings, when the men can be better spared than in the day-time.

Where there are not proper fruit-rooms, this sort of fruit may be kept in store-houses in baskets or hampers, placing soft paper in the bottoms and round the edges to prevent bruising them, laying a layer of fruit and a layer of paper alternately, covering the top with paper three or four times folded, to guard against the air and frost.

The different sorts of fruit should be packed separately, and have labels fastened to them, so as to know their names, and the times of their being in a proper state for use.

The best way of keeping fruit is, however, Mr. Forsyth thinks, by packing it up in glazed earthen pans or jars. In doing which, the fruit should be first separately wrapped in soft paper, then a little well-dried bran applied over the bottoms of the jars, above which a layer of fruit should be placed, continuing them alternately, till the jars are quite full, when they should be shaken, and a little more bran added, covering the whole over with bladders to exclude the air, putting on the covers, which should fit in a close manner. The rooms in which these are placed should be capable of admitting a fire in moist weather.

In packing fruit for carrying, Mr. Forsyth thinks strong deal boxes of different sizes the most convenient and useful. Those which he employs are two feet long, having the breadth and depth of fourteen inches; and one foot nine

inches long, with one foot in breadth and depth. They are constructed of inch-deal, well secured by cramps at the corners, having a small iron handle at each end to secure them by. In these, melons, currants, cherries, pears, peaches, nectarines, plums, grapes, and other similar sorts may be carried, the heaviest fruit of each sort being put at the bottom, the first sort wrapped up in soft paper, and all the others, except the currants and cherries, first in vine-leaves and then soft paper. The other two are conveyed in flat tin boxes, about fourteen inches in length, ten in breadth, and four in depth.

In packing them, for the melons, a layer of fine moss and short soft dry grass well blended together is placed at the bottom of the deal box, then the melons packed in with it in a tight manner in every direction, choosing them as much of the same size as possible. When the melons are put in, a thin layer of moss and grass is placed over them, upon which the tin box having the currants and cherries packed in it by intervening layers of fine dry moss, so as to be quite full, is packed firmly in with grass and moss all round to prevent its moving; over which another thin layer of moss is spread, and the pears packed in closely in the same manner as the melons, proceeding in the same way with the other fruits, so as to close with the grapes, filling up with moss, so as that the lid of the box may shut down quite tight, and prevent rubbing. Each box should be provided also with a lock, and two keys to serve the whole, one for the packer, and another for the emptier. When the boxes are locked down, they should be well corded.

In this manner his majesty's fruit is sent to different places, and may be conveyed to any part of the kingdom. When it is only sent a short distance, the moss and boxes should be returned, and be kept well aired.

FRUIT-GARDEN, that sort of garden which is principally planted with trees for the purpose of affording fruit of different kinds. The situation of this sort of garden should be warm sheltered, and open to the south or south-west, in order that it may enjoy the full benefit of the sun, and of course ripen the fruit in the best and most perfect manner. See **GARDEN** and **ORCHARD**.

FRUIT-ROOM, an erection constructed for the purpose of storing up different sorts of fruit. They are formed of different dimensions according to circumstances, being lined with thin boards, and fitted up with shelves, bins, boxes, drawers, and other conveniences for the reception of fruit; all of which, as well as the floors, should be of white deal, as Mr. Forsyth

remarks, that when red deal is made use of for these purposes, it is liable to give a disagreeable resinous taste to the fruit and spoil its flavour: on this account, under other circumstances, he advises covering the shelves with canvass, &c. as mentioned in the preceding article.

FRUIT-TREE, is that which produces eatable fruit, either for the table or culinary uses.

There are many fruit-trees, fruit-bearing shrubs and shrubby plants that ripen their fruit perfectly in this climate, with their several species, and numerous varieties: the principal sorts of which are those of the almond kind, as the almond, peach, and nectarine trees; the plum sort, containing different kinds of plum, apricot, and cherry trees, the pear kind, comprehending various sorts of pear, apple, and quince-trees; the vine, containing many sorts of grape-trees; the fig, comprehending many sorts of fig-trees; the several sorts of medlar-trees; the different kinds of mulberry-trees; the chestnut and walnut-trees; the common nut kind, containing many sorts of filberts and other nut-trees; the currant-, gooseberry-, and raspberry-trees, with many others; the nature and management of each of which will be fully explained under their respective genera.

FUCHSIA, a genus comprehending plants of the flowery exotic kind, for the stove.

It belongs to the class and order *Octandria Monogynia*, and ranks in the natural order of *Onagraceæ*.

The characters are: that the calyx is a one-leaved perianthium, funnel-form, coloured, superior, deciduous: tube ovate at the base, contracted above it, then gradually widening, patulous, angular: border short, four-parted; parts ovate, acuminate, spreading: the corolla has four petals, ovate, acuminate, sessile, spreading, the same length with the parts of the calyx: the stamina have four filaments (or eight) filiform, erect, inserted into the tube of the calyx below the middle, and a little longer than the tube: anthers twin: the pistillum is an inferior germ, ovate, below the insertion of the calyx constricted: style simple, the length of the stamens: stigma obtuse (club-shaped): the pericarpium is an ovate berry, four-grooved, four-celled: the seeds many, ovate, fixed in a double row to a columnar receptacle in the middle of the berry.

The species cultivated are: 1. *F. triphylla*, Three-leaved Fuchsia; 2. *F. coccinea*, Scarlet-flowered Fuchsia.

The first has a woody, branched, reddish root: the stem is herbaceous, upright, quite simple, reddish green, leafy, two feet high at most: the

leaves are lanceolate, entire, pale green, a little firm or coriaceous, sessile, disposed in threes: peduncles one-flowered, scattered, and forming a straight terminating raceme: the flowers large, very fine, of a very bright scarlet, having eight stamens, not projecting beyond the flower; and the berry is a little larger than an olive, fleshy, soft, reddish black, somewhat pubescent, of a very pleasant taste: the seeds small and brown. It is a native of St. Domingo.

The second species is a shrub, growing to the height of six or seven feet: the leaves are commonly opposite, on short petioles, of a fine green, having the veins tinged with red, with a fine down on them: the peduncles axillary, one-flowered, longer than the leaves: the flowers are pendulous, and of a bright scarlet colour. It is a plant of peculiar beauty, producing its rich pendent blossoms through most part of the summer: the petals in the centre of the flower are particularly deserving of notice, as they somewhat resemble a small roll of the richest purple-coloured ribband. It is a native of Chili.

Culture.—These plants are capable of being increased by seeds, layers, cuttings, and sometimes even by suckers. The seeds should be sown in pots of good light mould, plunging them into a bark hot-bed. When the plants appear, they should be kept clean, and be often refreshed with a little water. After they have attained a few inches growth, they should be shaken out of the former pots, and after being carefully separated and planted in separate small pots with the same sort of mould, be replunged in the hot-bed, and well shaded till they become fresh rooted, when air should be admitted pretty freely. They must be kept warm during the winter season.

The layers, cuttings, or suckers may be laid down or planted out in the latter end of summer or beginning of autumn.

They must all be kept in the stove during the winter season, but in the summer may be set out in the green-house.

They afford much ornament by their beautiful scarlet flowers.

FUMARIA, a genus containing plants of the tuberous-rooted low flowery perennial kind.

It belongs to the class and order *Diadelphia Hexandria*, and ranks in the natural order of *Corydalis*.

The characters are: that the calyx is a two-leaved perianthium: leaflets opposite, equal, lateral, erect, acute, small, deciduous: the corolla oblong, tubular, ringent, palate prominent, closing the throat: upper lip flat, obtuse, emarginate, reflex: the nectary the base of the upper lip prominent backward, obtuse: the lower lip en-

tirely similar to the upper, keeled towards the base: nectary the keeled base, but in this less prominent: the throat four-cornered, obtuse, perpendicularly bifid: the stamina consist of two equal filaments, broad, one within each lip, inclosed, acuminate: anthers three at the end of each filament: the pistillum is an oblong, compressed germ, acuminate: style short: stigma orbiculate, erect, compressed: the pericarpium is a one-celled silicle: the seeds are roundish.

The species are: 1. *F. cucullaria*, Naked-stalked Fumitory; 2. *F. sempervirens*, Glaucous Fumitory; 3. *F. lutea*, Yellow Fumitory; 4. *F. capnoides*, White-flowered Fumitory.

The first has a scaly root, the size of a large hazel-nut: the flower-stalk is eight or nine inches high: the root-leaves are in pairs, triternate, gashed, smooth, slender; with red petioles: the scape simple, round, length of the leaf, rufous: the raceme terminating, simple; the flowers (four or five) pendulous; of a dull white colour. It is a native of Virginia. Perennial, flowering in June and July.

The second species is annual: the stem upright, a foot and half high, round, and very smooth, sending out several branches at top: the leaves smooth, branching, pale, divided like the common sort, but the leaflets larger and more obtuse: the flowers in loose panicles from the sides of the stem and at the extremities of the branches, of a pale purple colour, with yellow chaps or lips: the pods are taper, narrow, an inch and half long, containing many small black shining seeds. It flowers during summer, and is a native of North America.

In the third, the root strikes deep into the ground: the stems are many, succulent, diffused, about six inches high: the leaves on long branching petioles, composed of many irregular leaflets, trifid at the top: peduncles axillary, naked, longer than the leaves, supporting eight or nine flowers, of a bright yellow colour, in a loose spike: the leaves continue green all the year, and the flowers in succession from April to October. It is very like the fourth species, but is perennial; and according to Miller, the stalks have blunt angles, are of a purplish colour; and the flowers grow in a looser panicle, on longer pedicles. It is a native of Barbary.

The fourth is annual: the stem four-cornered at the base: the leaves superdecompound, the terminating leaflets larger, and semitri-fid; the middle segment lobed; petioles three-cornered: the racemes naked; pedicles shorter by half than the corollas, blackish at the tip. There is a succession of the flowers from May

F U M

to October. It is a native of the South of Europe.

Culture.—The first sort of these plants may be readily increased, by planting off-sets from the roots in a light soil, in a shady situation, in the beginning of autumn, as soon as the stems begin to decay.

The other sorts may be raised by sowing the

F U M

seeds where the plants are to grow, as soon as they become perfectly ripened.

The only culture they demand afterwards is, that of keeping them free from weeds.

They are all very ornamental in the fore parts of clumps, borders, and other parts of pleasure-grounds.

FUMITORY. See **FUMARIA**.

G A L

GALANTHUS, a genus containing a plant of the bulbous-rooted flowery perennial kind. It belongs to the class and order *Hexandria Monogynia*, and ranks in the natural order of *Spathaceae*.

The characters are: that the calyx is an oblong spathe, obtuse, compressed, gaping on the flat side, withering: the corolla has three petals, oblong, obtuse, concave, lax, patulous, equal: nectary cylindric, three-leaved, half the length of the petals; leaflets petal-shaped, parallel, emarginate, obtuse: the stamens consist of capillary filaments, very short: anthers oblong, acuminate, ending in a bristle, convergent: the pistillum is a globular, inferior germ: style filiform, longer than the stamens: stigma simple: the pericarpium is an oval-globular capsule, obtusely three-sided, three-celled, three-valved: the seeds several and globular.

The species is *G. nivalis*, Snow-Drop.

It has the bulb coated and truncate: the leaves are yellowish at the base, callous at the tips: the scape half a foot or a span in height, ancipital, striated, involved at the base in a pair of leaves: the sheath whitish, truncate, involving the leaves and scape: the peduncle usually comes out from the left cell of the spathe, is weak, and wrinkled below the germ: the flowers are solitary, and of a milk-white colour. It is a native of Switzerland, flowering in January and February.

It varies with semi-double, and with double flowers.

Culture.—These little elegant plants are increased by planting off-sets from their roots in the places where they are to remain in the latter end of summer, when their leaves begin to decline, or in the beginning of the autumn. The roots should not, however, be removed oftener than every third year.

G A R

They should always be planted in bunches of a great number of bulbs together, in order to make a better show, as when set out singly they have no effect.

They are well adapted to the fronts of borders and clumps, as well as woody and shady plantations, producing a fine effect when in blow.

The single sorts come first into blow.

GARDEN, a portion of ground laid out for the purpose of raising and providing different sorts of plants of both the flowery and esculent kinds, as well as various other vegetable productions and fruits.

It is usually distinguished, from the nature of the produce, into the Flower- and Kitchen-garden; the latter being chiefly destined to the raising of useful culinary roots, plants, and vegetables.

Where the first sort of gardens are necessary, they should be laid out so as to have open sunny sheltered exposures, forming if possible the connections between the ornamented or pleasure-grounds, and the kitchen-gardens, according to the general nature and situation of such grounds, so as to afford the most striking effect and variety.

Their forms may vary in proportion to the distribution of the lands and the particular circumstances of their situations, being made square, circular, oblong, or in any other manner, according to the taste of the proprietor; the parts approaching the ornamented grounds being mostly separated by walks, and the introduction of different sorts of the most curious hardy flowering shrubby plants. The interior parts should have a neat ornamental distribution, so as to produce the most striking variety when the flowers are in blow, and afford the greatest convenience in their cultivation. It was formerly the practice to have them laid out with walks surrounding the outer

boundaries or borders being introduced all round within them, and the inner compartments divided into a variety of narrow straight borders or plain four-feet wide parallel beds, having two-feet wide alleys between; the whole of them being laid in a rounding form, and neatly edged with dwarf box, or some other plant suited to the purpose; and the walks and alleys laid with the finest sand; but at present they are mostly arranged so as to suit the nature of the situation, produce the most ornamental effect, and afford the greatest ease, convenience, and success in the culture of the flowers.

They should contain all the different sorts of hardy curious ornamental flower plants, whether of the bulbous, tuberous, or fibrous rooted kinds.

The second division, or kitchen-garden, must be laid out in different methods, according to the differences in the circumstances of the ground. It is sometimes so managed as to constitute a part of, or communicate with, the pleasure-ground; but where there is sufficient extent of land, it is better to be distinct, or detached from it, and in every case as much concealed from the house as possible. The most convenient distribution is at some distance behind it; but on the sides may answer very well, especially when not too contiguous, or so situated as to interrupt any particular prospect.

In regard to the nature of the situation most proper for the purpose, it should, when convenient, be where there is a gentle declination towards the south or south-east, in order that it may have the full advantage of the morning sun. Mr. Forsyth remarks in his "Treatise on the Culture and Management of Fruit-trees," that "if it be situated in a bottom, the wind will have the less effect upon it; but then the damps and fogs will be very prejudicial to the fruit and other crops;" and that when "situated too high, although it will in a great measure be free from damps and fogs, it will be exposed to the fury of the winds, to the great hurt of the trees, by breaking their branches, and blowing down their blossoms and fruit." It should therefore, in his opinion, "be well sheltered from the north and east to prevent the blighting winds from affecting the trees, and also from the westerly winds, which are very hurtful in the spring or summer months." Where it is not "naturally sheltered with gentle rising hills, which are the best shelter of any, plantations of forest-trees should," he says, "be made at proper distances, so as not to shade it." These, he supposes, will be found the best substitute, but at the same time the sun and air should be freely admitted. On this account it is supposed that "a place sur-

rounded by woods is a very improper situation for a garden or orchard, as a foul stagnant air is very unfavourable to vegetation." It is likewise added that "blights are much more frequent in such situations than in those that are more open and exposed." In these sheltering plantations, Mr. Forsyth advises that fruit-trees should be intermixed with those of the forest kind, which, besides being advantageous in the way of affording shelter, ornament, and fruit, become nurseries for raising forest-trees.

But where the situations will not admit of this, he suggests the propriety of planting some cross rows of fruit-trees in the garden at the distances of about forty or seventy yards from each other, more or less, in proportion to the extent: where the length is considerable, one row may be sufficient on each side, but in short cross rows two on each side the walks or paths. In this intention the trees should not be planted opposite one another, but in such a manner as that those in one row may be opposite to the middle parts of the open spaces in the others. In this method, besides the ornamental effect that is produced, the force of violent winds is broken, and much damage to other trees prevented.

In this view, the best sort of trees, according to Mr. Forsyth, is that of dwarfs, with stems about two feet high, which may readily be provided by removing the lower branches.

In fixing upon ground for a garden, it is likewise a point of much importance to have the natural soil of a good quality, being sufficiently dry, mellow, and capable of being easily wrought in all seasons, as well as of a good depth, as from a foot and half to three feet. And if the surface be uneven, it will be the better, as there will be a greater variety in the quality, and of course it will be more fully adapted to the culture of different crops. The most proper sort of soil for this purpose is that of the rich friable loamy kind, and the worst those of the very light, sandy, and stiff clayey descriptions. But the properties of soils may be much improved in most cases by a judicious application of different sorts of materials in the way of manure. See SORT and MANURE.

Where fruit-trees, especially those of the finer, as well as apple and pear kinds, are to be planted, a greater depth of good soil, as well as a greater degree of dryness, is necessary.

There are very different opinions in respect to the most proper and advantageous forms for this sort of culture; but though much must constantly depend on the nature of the situation, where the spade is to be made use of in performing the work, the square shape, or that which

approaches nearest to it, is probably the most convenient. In other cases, especially where the principal part of the work is, from the difficulty of procuring labourers, and the increasing expense of them, to be executed by the plough, the oblong and circular forms may be the most suitable, as they may be wrought with greater facility and convenience.

The size of kitchen-gardens should always be fully sufficient for the extent of the family, varying from half an acre, to four, five, or more, within the fence. The first quantity, where there are wall and espalier trees, will furnish sufficient employment for one man, and afford due supplies of vegetables and fruit for families consisting of a dozen or more persons. But much in these respects depends upon proper care and management.

The best mode of inclosing garden-ground is by means of brick walls, where that sort of material can be easily procured, and expense is not an object. But oak paling fences answer the purpose very well. These fences, whether made of brick or wood, should be eight, ten, or twelve feet in height. When the extent of walling is sufficient, Mr. Forsyth thinks ten feet walls better than such as are higher, as being more convenient for various purposes. He also advises that they should have borders or slips on the outsides of them, of from forty to sixty feet or more in breadth, where the ground can be spared, which should likewise be inclosed by an oak paling, six or eight feet in height, having a chevaux de frise at the top to strengthen the fence and render the garden more secure. The latter may be conveniently formed, he says, by planing a piece of wood four inches in breadth, and an inch and quarter in thickness, into the shape of the roof of a low pitched house on the upper side, then drawing a line on each side from end to end, at the distance of about an inch and quarter from the upper edge, driving twelve-penny nails through them in regular rows, at the distance of four inches from each other, so as to come out near the upper edge of the contrary side; each being opposite the middle of the space between two nails on the other side. The nail heads should be sunk, and strips of wood nailed over them, tenter-hooks being driven in between the nail points, and the whole nailed fast to the outside top of the fence; continuing pieces in this way till the whole is completed.

By means of these inclosed borders or slips on the outside of the garden walks, Mr. Forsyth thinks there will be plenty of ground for gooseberries, currants, and strawberries, and both sides of the walls may be planted with trees,

by which there will be a considerable increase of wall-fruit. And where there are parts of such slips lying near to the stables, sufficiently sheltered and exposed to the sun, they may be converted to the purpose of a forcing ground for raising melons, cucumbers, and other similar kinds of fruit.

The advantages of this are, that there will be no litter carried within the walls, to dirty the walks; the beds will be concealed from the sight, and much time and labour saved in carting and wheeling the dung.

Where there are not these sorts of slips, the forcing-grounds for melons, cucumbers, &c. should be made in situations that are warm, and open to the full influence of the sun, being well inclosed, and as contiguous to the stable as the nature of the situation will allow.

The great objection to having slips or borders on the outsides of the walls of gardens is that of the vast expense of erecting two fences, where one is capable of answering the purpose, and by proper attention in the distribution of the internal parts, with perhaps nearly equal advantage.

In the distribution of the quarters or parts of the garden, attention should be had to the nature, form, and extent of the ground, so as that they may be laid out in the best manner, in respect to the convenience of managing them, exposure, and size; but they should never be made too small, as there will be much loss of ground by the walks which are essentially necessary in their cultivation. With regard to their form, it may vary according to circumstances, or the taste of the proprietor; but the most convenient and economical one, in respect to ground, is the square, where the garden has been laid out in that manner.

It is usual to have borders round the whole of the inclosing fences, whether they be constructed of brick, stone, or timber; and when there are cross walls, they are likewise generally introduced on the sides of them. The breadths of these should be proportioned to the height of the walls or palings, and the extent of the garden, as from six, to eight, ten, and twenty feet, especially those which have a southern aspect, and are intended for the reception of fruit-trees, as their roots will have more room to extend themselves and procure due nourishment. Besides, wide borders are the most advantageous and economical in the culture of different vegetable crops.

When the gardens are large, other borders may be carried along on the sides of the walks, between them and the espalier or standard fruit-trees; but in other cases this is inconvenient, as taking up too much of the quarters. These

should not exceed six or eight feet in breadth.

In some cases it is the practice to have the edges of the border made firm and even, and planted with dwarf box, or some other plant made use of for the purpose; but as these sorts of edgings are very liable to be destroyed in different places by wheeling over them, and by that means become unsightly, it is probably a better method to only have the edges of the border made up firm and even, close to the gravel of the walks.

There should be a walk introduced on the sides of the borders all round, and likewise in the middle, where the ground is of considerable extent. Cross walks are also necessary where the garden has a great length. But as walks take up much ground, there should be as few as possible. Those on the sides of the borders need not have more breadth than from four to six feet; but the middle ones should be seven feet wide, in order that a cart may be admitted when necessary.

It is also necessary to have walks about two feet or two feet and a-half wide, and the same distance from the walls, where there are wall-trees, for the convenience of pruning, training, and nailing, as well as that of gathering the fruit, and admitting a barrow or garden-engine for watering them.

And besides these permanent walks, when the gardens are of much extent, trodden path-walks will be requisite in different parts, for the convenience of cultivation, and as divisions between the crops.

All the first sort of walks should be laid out in a regular manner, and be firmly made up with brick rubbish, stone-masons' chippings, or some other coarse material, and neatly gravelled over. For this last purpose binding-sand answers extremely well, also good clean sifted road drift, as they may be readily kept clean by the hoe and rake; but sea-coal ashes are preferred by some, as being still more dry and firm, more easily kept in order, and cleaner to walk upon in thaws, as well as useful, while new and rough, in preventing slugs from travelling over them from the different quarters.

The narrow walks on the back sides of the borders, near the fruit-trees, need not be laid with any sort of coarse rubbish, being merely covered over to the depth of a few inches with sand or sea-coal ashes; as by this means the ground may be occasionally dug up, and the paths relaid.

Whatever sort of material is made use of in forming the walks, it should be spread in a neat even manner, so as to leave them in a re-

gular moderate convex or rounded form, by which the water will be readily carried off to the sides, and the walks kept perfectly dry. After the surface material has been thus applied, and evenly raked over, it should be firmly rolled down by a heavy iron roller, and occasionally repeated after being well moistened with rain.

Sometimes walks are laid with turf or sward; but this is a very improper material, as being troublesome to keep in order, and soon rendered disagreeable to the sight by being wheeled and trampled upon.

In building the walls of kitchen-gardens, when the height is considerable, the foundation should be from two to two bricks and a half in thickness, and the offset not more than one brick above the height of the level of the border, being then brought to a brick and half in thickness: when they are extensive they should be strengthened and supported by piers at the distance of from forty to sixty feet, according to their height. The projection of these piers should not be more than about half a brick before the surface of the wall. Walls for fruit-trees should always, if possible, be built of brick, as stone is found not by any means so favourable to the maturation of the fruit, and far more inconvenient in the nailing of the trees. The manner of constructing hot-walls for bringing fruit forward by artificial heat will be described hereafter. See HOT-WALL.

Some advise projecting copings of stone or wood to be fixed upon the tops of the walls; and the author of the "Philosophy of Gardening" conceives that they may be of great utility in the early vernal months in preventing the tender young shoots of fruit-trees from being destroyed by frost, as, from their being less imbued with the night-dews in consequence of them, they will be less exposed to danger from that cause; it being well ascertained that the fine shoots of vegetables are most exposed to the destruction of frost when in a moist state.

Mr. Forsyth does not however approve of such fixed copings, especially when they project so far as is usually the case; moveable wooden ones fastened by iron hooks to pieces of wood built into the tops of the walls being in his opinion preferable. Besides, they are useful to fix nettings, &c. to in the early spring for protecting the trees with. When fixed copings are adopted, they should not, he thinks, extend above an inch on each side the wall, as the slight projection will be sufficient to preserve it, and at the same time not prevent the dews and rains from falling upon the upper parts of the trees, by which they are greatly benefited. Copings are sometimes formed of a sort of

brick, made convex on the side which is upwards; but these are expensive. A sort of slate, brought from Wales, has lately been made use of for this purpose, which seems to answer very well. It is made to have the projection just mentioned. This sort of coping has been employed in the extensive gardens at Ashsted Park, near Epsom; and may be had of different sizes at Mr. Samuel Wyatt's slate-wharf, near Blackfriar's Bridge. Mr. Forsyth suggests that common copings should have a little slope given them "towards the north or east, according to the aspect of the wall," by which the wet from the south and west sides may be taken away, and the danger of the early blossoms and fruit being injured on the south and west walls in cold nights be avoided.

When the soil of a garden is naturally of a stiff quality and retentive of moisture, proper under-draining will be essentially necessary in order to the production of good well-tasted fruit, as well as fine culinary vegetables. In these cases the main or leading drains should be made under the walks, and those from the quarters be formed to communicate with, and empty themselves into them. They should be constructed of bricks, either common or such as are formed for the purpose, and be laid in such directions as are the best adapted to the removal of the injurious wetness, and always of such depths as to prevent their being injured by the spade in working the ground. By this means the soil will be kept in a suitable state for the growth of the plants, and the walks preserved in a fine state of dryness, so as to be sufficiently firm for carting or wheeling upon, even in wet seasons.

When the ground destined for the purpose of forcing is on a level considerably lower than that of the garden, the water from the latter may be made to supply the former, by having the main leading drain terminating in a tank, pond or cistern constructed in it for the purpose, which in many situations may be extremely convenient and useful.

In many cases, and especially where the garden-grounds are of a dry quality, it is of vast advantage to have them situated contiguous to rivers, brooks, or large basons of water, from which they can be supplied by means of drains, pipes, or other contrivances, in the most hot and droughty seasons.

Where no supplies of water can be provided and brought to the garden in these ways, Mr. Forsyth suggests that where they lie on the sides of public or other roads, and the level of the grounds is suitable, hollow drains should be formed in the most convenient parts, to receive the water that washes them in rainy seasons,

and convey it to large ponds or other places made for its reception in the highest part of the garden-ground that will admit of it; from which it may be dispersed to the different quarters which will allow of it, by pipes, with cocks fixed at different places for turning it on as may be necessary. Or by having suitable channels cut, it may be turned upon different parts, as in the practice of watering meadow land, which, where the roads are repaired with calcareous materials, or there is much vegetable matter washed down them, may be highly beneficial in the way of manure. A proper ready exit for the superabundant water must always be provided in these cases, to prevent stagnation. And where the ground has been much enriched by stable manure, the practice should be cautiously adopted, as more may be conveyed away in the state of solution than is brought by the water. The most convenient time for turning on water is generally during the night, which in dry seasons is the most advantageous to the plants or crops.

The expense in pipes, drains, channels, and other apparatus for these purposes, will be considerable at first; but the saving in labour and time in the pumping and carrying water, it is conceived, will soon repay it. Where water is under the necessity of being pumped up from deep wells, large basons or reservoirs should be provided, in which it should remain some time exposed to the influence of the atmosphere before it is made use of in the above or any other way.

When garden-grounds are of a wet spewy quality, Mr. Forsyth recommends basons to be formed in the most convenient parts, for the reception of the water that proceeds from the drains, and which falls in rain on the walks and paths.

In new kitchen-garden grounds, where the soil is of a strong stiff heavy quality, they should be ploughed or trenched over three or four times, being exposed to the effects of frost, in pretty high ridges, for a winter, in order to bring them into a proper condition, before the crops are put in. A crop of potatoes or beans also assists greatly in bringing them into a proper state of pulverization for being planted upon with culinary vegetables.

When the land is become sufficiently broken down and reduced, the wall- and other trees, as well as different sorts of vegetable crops, may be put in. Some, however, put the fruit-trees in before this has been accomplished; but it is not a good practice, as they are liable to be injured by the digging which afterwards becomes necessary in preparing the soil.

In planting wall-trees they should be set at

different distances according to the kinds: those of the peach, nectarine, apricot, plum, and cherry descriptions, at fifteen, eighteen, or more feet, and for figs and pears twenty are seldom too much, suitable aspects being chosen according to the kinds. Between their wall-fruit trees, some at first introduce half or full standards, that the walls may at once be covered, removing them afterwards. But this is a method that should never be attempted when it can be avoided.

Trees of the espalier kind are likewise frequently introduced in ranges round the main quarters at the distance of about six feet from the side of the walk, and from fifteen to twenty in the rows, according to the sorts that are made use of. Within these ranges of espalier trees, good standards of tall growth are occasionally introduced at the distance of thirty, forty, or more feet in each direction. Where there are orchards, this should, however, always be avoided. See the **CULTURE OF THE DIFFERENT KINDS**.

Fruit-trees of the small shrubby kinds, such as gooseberries, currants, raspberries, &c., where there are not out-slips, are frequently introduced on the sides of the quarters, and as divisions to them when large, at the distance of eight or nine feet from each other. When planted in this way, they should be trained in the fan form. But it is better, where it can be done, to have them in separate plantations, especially the first sort. See the **CULTURE OF THE SEVERAL SORTS**.

In respect to the distribution of the vegetable crops, it must be regulated by the nature of the situation, their particular kinds, as well as the taste and experience of the gardener. On the narrow borders under the wall-trees, various sorts of small crops may be grown, both of the early and late kinds, according to the difference of the aspects; but all the deep rooting sorts should be avoided, such as cabbages, cauliflowers, beans, and peas, except those of the frame kind, as being injurious to the trees by the shade which they cause, as well as by depriving them of due nourishment.

But the large part of the borders next the walks is proper for raising all sorts of the more early crops, such as those of the radish, lettuce, spinach, carrots, French bean, salad herb, and all the dwarf pea kinds that are cultivated in wide rows; those which have a southern aspect for the earliest crops; and the eastern and western ones for succession crops of the several kinds; and the northern ones, as being more cool, for raising and pricking out many sorts of small plants, slips, and cuttings, in the

summer season, when the other parts are apt to be too dry.

Such borders as are next to the ranges of espalier trees, are well suited to the different low growing crops, such as lettuce, spinach, endive, strawberries, &c. and for pricking out upon, at different seasons, many sorts of plants to be afterwards transplanted into different situations.

The quarters or large divisions should always be destined for the reception of the large principal crops, such as those of the onion, leek, carrot, parsnip, turnip, beet, potatoe, cabbage, cauliflower, brocoli, colewort, kale, pea, bean, scarlet-bean, clery, artichoke, asparagus, and other similar kinds.

The preparation of the ground, the methods of manuring, and putting in the crops, with their modes of after-culture and management, are fully explained under their respective genera.

In every department the greatest attention should be paid to the keeping of the different parts fully cropped, as well as to neatness and regular order; and as the crops are removed from the ground in the autumn, it is often of great advantage to have it ridged up for the winter.

When the garden has been thus laid out, planted, and finished, Mr. Forsyth has found much advantage from having a plan of it, with the names of the different trees introduced in their proper places. By this means the memory is greatly assisted, especially in extensive grounds, and the various operations performed with more regularity and exactness. The annexed plate contains the **PLAN OF AN IMPROVED GARDEN**.

GARDEN ENGINE, a sort of pump, contrived for the purpose of watering different sorts of wall or other trees. See **WATERING-ENGINE**.

GARDEN FRAME. See **FORCING-FRAME** and **FRAMR**.

GARDEN IMPLEMENTS, various sorts of tools made use of in the business of practical gardening. See **PLATE ON GARDEN IMPLEMENTS**.

GARDEN ROLLER. See **ROLLER**.

GARCINIA, a genus containing a plant of the tender exotic tree kind for the stove.

It belongs to the class and order *Dodecandria Monogynia*, and ranks in the natural order of *Bicornes*.

The characters are: that the calyx is a four-leaved perianthium: leaflets roundish, concave, obtuse, spreading, permanent: the corolla has four roundish petals, concave, spreading, a little larger than the calyx: the stamina consist of sixteen filaments (twelve or more), upright;

placed in a cylinder, simple, shorter than the calyx: the anthers roundish: the pistillum is a superior germ, suboval: style scarcely any; stigma flat, spreading, peltate, eight-cleft, obtuse, permanent: the pericarpium is a coriaceous berry, globular, large, one-celled, crowned with the stigma: the seeds eight, convex on one side, angular on the other, villose, and fleshy.

The species cultivated is *G. Mangostana*, Mangostan or Mangosteen.

It rises in its native situation with an upright stem near twenty feet high, sending out many branches on every side, which are placed opposite, and stand oblique to each other, and not at right angles; the bark of the branches is smooth, of a gray colour; but on the tender shoots it is green, and that of the trunk is of a darker colour, and full of cracks: the leaves are entire; they are seven or eight inches long, and about half as much in breadth in the middle, gradually diminishing to both ends, of a lucid green on their upper side, and of an olive colour on the under, having a prominent midrib through the middle, with several small veins running from that to both sides of the leaf. The flower is like that of a single rose, composed of four roundish petals, which are thick at their base, but thinner towards their ends, and of a dark red colour. The fruit is round, the size of a middling orange, the top being covered by a cap. It has a delicious flavour, partaking of the strawberry and grape; being esteemed one of the richest fruits in the world. It is a native of the Molucca Islands.

Culture.—These plants are increased by sowing the seeds in pots filled with light mould, in the situations where they grow naturally, being afterwards brought hither, and when the plants are of sufficient growth removed into separate pots, and plunged in the bark-bed of the stove, due shade being given till they become well established. They should afterwards be managed in the same way as tender exotics.

They are also capable of being increased by planting cuttings of the young shoots in pots of light earth, and plunging them in the bark-bed.

The plants afford variety in stove collections.

GARDENIA, a genus containing a plant of the flowering shrubby kind for the stove.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Contortæ*.

The characters are: that the calyx is a one-leaved five-cleft perianthium, superior: divisions upright, permanent: the corolla is one-petalled, funnel-form, or salyer-form: tube cy-

lindric, longer than the calyx: border flat, five-parted: the stamina have no filaments: anthers five, inserted into the mouth of the tube, linear, streaked, half the length of the border: the pistillum is an inferior germ: style filiform or club-shaped: stigma standing out, ovate, obtuse, two-lobed, often furrowed: the pericarpium is a berry (berryed drupe), dry, one-, two-, or four-celled: the seeds very many, flattened, imbricate, in rows (two rows in each cell).

The species cultivated are: 1. *G. florida*, Fragrant Gardenia, or Cape Jasmin; 2. *G. aculeata*, Round-leaved Gardenia.

The first has a large and woody stem, sending out many branches, which are first green, but afterwards the bark becomes gray and smooth; the branches come out by pairs opposite, and have short joints; the leaves also are opposite, close to the branches; they are five inches long, and two inches and a half broad in the middle, lessening to both ends, terminating in a point; they are of a lucid green, having several transverse veins from the midrib to the borders; they are entire, and of a thick consistence. The flowers are produced at the ends of the branches, sitting close to the leaves. When fully blown, the double flower is as large as a middling rose. It has a very agreeable odour on the first approach, something like that of the orange-flower, but, on being more closely smelt to, like the common double white Narcissus. It is a native of the Cape, flowering in July or August.

It varies with single and double flowers.

The second species is a small shrub rising by a branched stalk, and shooting commonly to the height of seven or eight feet; the main stem tough and hard; the branches somewhat prickly at the ends; the leaves of an oval form, and growing in tufts. It is a native of the West Indies.

Culture.—The first sort may be increased by planting cuttings of the young shoots in pots of light rich mould, in the summer season, plunging them in a moderate tan hot-bed, and covering them close with bell-glasses, giving due shade till they have stricken root. When this has been fully effected, they should be carefully removed into separate small pots, and replunged in the hot-bed. When they are become well established, they should be gradually inured to the influence of the air.

The second sort may be raised by sowing the seeds in pots filled with light fresh earth in the early spring months, plunging them in a bark hot-bed, frequent slight waterings being given. After the plants come up they should have free air in fine weather, and be often watered. When of some growth they should be carefully re-

moved into separate pots, and be replaced in the hot-bed, due shade being given till they are re-established, when they must have air and water in proportion to the warmth of the season. As the autumn approaches they should be removed into the bark-bed of the stove, where they are best kept the two first seasons; but they may afterwards be exposed in the open air in the hot summer months.

These plants are valuable for the variety which they afford in stove collections.

GARLICK. See **ALLIUM**.

GARLICK-PEAR. See **CRATEVA**.

GELDER ROSE. See **VIBURNUM**.

GENISTA, a genus containing plants of the low shrubby deciduous and evergreen kinds.

It belongs to the class and order *Diadelphia Decandria*, and ranks in the natural order of *Papilionaceæ*.

The characters are: that the calyx is a one-leaved perianthium, small, tubular, two-lipped: upper lip two-toothed, more deeply divided; lower three-toothed, nearly equal: the corolla is papilionaceous: banner oblong, remote from the keel, the whole reflex: wings oblong, loose, shorter than the others: keel straight, emarginate, longer than the banner: the stamina have ten filaments, connate, emerging from the keel: anthers simple: the pistillum is an oblong germ: style simple, rising: stigma sharp, rolled in: the pericarpium is a roundish legume, turgid, one-celled, two-valved: the seeds solitary, usually kidney-form.

The species chiefly cultivated are: 1. *G. tinctoria*, Common Dyer's Genista, or Broom; 2. *G. sagittalis*, Jointed Genista, or Broom; 3. *G. florida*, Spanish Dyer's Genista, or Broom; 4. *G. pilosa*, Hairy Genista, or Broom; 5. *G. Anglica*, English Genista, Petty-white, or Needle-Furze; 6. *G. candicans*, Hoary Genista, or Montpellier Cytisus; 7. *G. Canariensis*, Canary Genista, or Cytisus.

In the first the roots creep far and wide. The stems are many, angular, tough, from a foot to eighteen inches or two feet in height, sometimes more; the branches subdivided, ending in short spikes of yellow flowers, with stipules between them. The leaves alternate, sessile, quite entire, acuminate, an inch long, and two lines broad, smooth, except that the edges and the nerve underneath are slightly villose. It is a native of most parts of Europe.

The second species sends out several stalks, which spread flat on the ground, and divide into many flat branches which are jointed, and their two sides are edged like a broad-sword; they are herbaceous but perennial. At each of the joints is placed one small sessile spear,

shaped leaf, ending in a point, of a deep-green colour and smooth. The flowers are produced in close spikes at the ends of the branches, and succeeded by short hairy pods, which contain three or four kidney-shaped seeds. It is a native of France.

The third rises with woody stalks two or three feet high, sending out many taper channelled branches, which grow erect. The leaves are small, alternate. The spikes of flowers terminating; succeeded by short pods, which turn black when ripe, and contain four or five kidney-shaped seeds. It is a native of Spain, flowering in June and July.

The fourth species differs from the first in having the branches depressed on every side and procumbent, while that is upright. The root is long, running obliquely, and furnished with many small fibres. The stem a foot in length or more, much branched, and tough; the old branches naked, the young ones clothed with numerous, minute, oval or oval-lanceolate leaves, entire, smooth on the upper surface, beneath covered with long white silky hairs. The flowers are in short spikes on the summit of the branches, on short hairy peduncles. It is a native of Sweden, flowering in May.

The fifth has the stem much branched: the branches tough, without leaves, furnished with extremely sharp slender thorns, from a quarter to half an inch in length; the shoots of the year grow in bundles on the summits of the old ones, and sparingly from the sides, bearing numerous, small, light green, oval or lanceolate, smooth, entire leaves, intermixed with soft spines. The flowers are small, pale yellow, and few. It is a native of Britain.

The sixth species rises to the height of seven or eight feet, sending out many slender branches, the upper parts of which, for more than a foot in length, send out small flowering-branches on their sides, supporting five yellow flowers, which appear in June and July. It is a native of Spain.

The seventh has the leaves obovate, somewhat mucronate; but the floral leaves subsessile and minute. The calyx is trifid, the lowest segment three-toothed. The flowers are in corymbs, five or six together, and sweet-scented. It is a native of the Canaries.

Culture.—The first six hardy sorts are all capable of being raised by sowing the seeds in beds of common earth, or, which is better, in the places where they are to remain, in the early autumn or spring; but the former is the more advantageous, as much time will be saved. Where raised in beds, the plants must be carefully taken up and removed, when they have

had a twelvemonth's growth, to the places where they are to remain; but in the other method require no other culture, but proper thinning out and being kept clean.

The last sort may be increased by sowing the seeds in pots of good mould in the spring, plunging them in a moderate hot-bed. When the plants have attained a few inches in growth, they should be removed into separate pots, and be replunged in the hot-bed. They afterwards require the same sort of management as other less tender green-house plants.

All the first sorts are well adapted to the fronts and other parts of clumps and borders in ornamented grounds, by their flowery nature; and the last affords a fine effect in the green-house by its evergreen property.

GENTIAN. See **GENTIANA.**

GENTIANA, a genus of plants of the hardy herbaceous perennial flowery kind.

It belongs to the class and order *Petandria Digynia*, and ranks in the natural order of *Rotaceæ*.

The characters are: that the calyx is a five-parted perianthium, sharp: divisions oblong, permanent: the corolla has one petal, tubular at bottom, imperforate, at top five-cleft, flat, withering, various in form: the stamina have five filaments, subulate, shorter than the corolla: anther simple: the pistillum is an oblong germ, cylindric, length of the stamens: styles none: stigmas two, ovate: (germ superior; style simple, or two sessile stigmas.) the pericarpium is an oblong capsule, columnar, acuminate, slightly bifid at the tip, one-celled; two-valved: the seeds numerous, small, fixed all round to the walls of the capsule: receptacles two, each fastened longitudinally to a valve.

The species cultivated are: 1. *G. lutea*, Yellow Gentian; 2. *G. punctata*, Spotted-flowered Gentian; 3. *G. asclepiadea*, Swallow-wort-leaved Gentian; 4. *G. acaulis*, Dwarf Gentian, or Gentianella.

The first has a thick root, of a yellowish brown colour, and very bitter taste: the lower leaves are petioled; oblong-ovate, a little pointed, stiff, yellowish green, having five large veins on the back, and plaited: the stem three or four feet high or more, with a pair of leaves at each joint, sessile or almost embracing, of the same form with the lower ones, but diminishing gradually to the top: the flowers are in whorls at the upper joints. It is a native of Switzerland, flowering in June and July.

The second species has the leaves ovate, elongated, and strict: the calyxes shallow, and in form of a basin, the calycine teeth narrow, sharp, and not very leafy: the corolla is of a

papery substance, extremely thin, of a dull and very pale greenish straw-colour, with very minute dots thickly and irregularly scattered over it: the segments of the border commonly seven, sometimes eight, but very seldom six, always shorter, narrower, contiguous, rounded, blunt, without any auricles at the base; and finally the bellying of the corolla is blunter and almost the same over the whole bell. It is a native of Austria.

The third has the stem upright near a foot high: the leaves smooth, about two inches long, and three quarters of an inch broad at the base, embracing there, and ending in an acute point; they are of a fine green, have five longitudinal veins, joining at both ends, but diverging in the middle, and diminish in size as they are nearer the top: the flowers are in pairs opposite, on short peduncles; pretty large, bell-shaped, and of a fine blue colour. It is a native of Switzerland, flowering in July and August.

The fourth species has a large woody branched root: a set of ovate-lanceolate leaves spreads on the surface: the stem from one to three inches in height, with one or two pairs of leaves on it, and terminated by one very large, upright, handsome flower (in the garden, when the plants are strong, there are sometimes more,) which is of a deep azure blue, dotted on the inside. It is a native of Austria.

Culture.—The three first sorts are easily raised, by sowing the seed in pots soon after it is ripe, as when kept till the spring it will not succeed: the pots should be placed in a shady situation, and kept clean from weeds. Some advise their being sown where they are to remain, but the first is probably the best method. In the spring the plants appear, when they must be duly watered in dry weather, and kept clean from weeds till the following autumn; then be carefully shaken out of the pots, so as not to break or injure their roots; and a shady border of loamy earth should be well dug and prepared to receive them, into which they should be put at about six inches distance each way, the tops of the roots being kept a little below the surface of the ground, and the earth pressed close to the roots. If the following spring prove dry, they should be duly watered, to forward their growth. The plants may remain here two years, by which time they will be fit to transplant where they are designed to grow, removing them in the autumn, as soon as their leaves decay, great care being taken in digging them up, not to cut or break their roots, as that greatly weakens them. They require afterwards no other culture, but to dig the ground about them early in the spring before they begin to shoot, and in the summer to keep

1 *Gentiana acanthus.*
Large flowered Gentian.

2 *Glycine rubicunda.*
Daisy-flowered Glycine.

them clean from weeds. The roots continue many years, but the stalks decay every autumn; the same roots not flowering two years together, or seldom oftener than every third. When they flower strong, they have, however, a fine appearance.

The first is mostly propagated by off-sets or parting the roots, and planting them where they are to remain in the early autumn; but in order to have the plants flower well, they must not be often transplanted or parted.

They are also capable of being raised from seeds managed as the first sorts.

They all succeed the most perfectly in moist loamy soils, where there is a degree of shade.

All the sorts are useful as ornamental plants, for the various clumps, borders, and quarters of pleasure-grounds; those of low growth being planted towards the fronts, and the latter kinds more backward.

GERANIUM, a genus containing plants of the herbaceous perennial kinds.

It belongs to the class and order *Monadelphia Decandria*, and ranks in the natural order of *Grinales*.

The characters are: that the calyx is five-leaved: leaflets ovate, acute, concave, permanent: the corolla has five petals, obcordate or ovate, spreading, regular: nectary five honeyed glands, fastened to the base of the longer filaments: the stamina consist of ten filaments, awl-shaped, connected slightly at the base, spreading at top, shorter than the corolla: anthers oblong, versatile: the pistillum is a five-cornered germ, beaked: style awl-shaped, longer than the stamens, permanent: stigmas five, reflex: the pericarpium is a five-grained capsule, beaked, the cells opening inwards, each having a simple naked tail fixed to it: seeds solitary, and ovate-oblong.

This extensive genus has been subdivided into *Erodium* with five, and *Pelargonium* with seven fertile stamens.

The species are: 1. *G. phœum*, Dark-flowered Crane's-Bill; 2. *G. nodosum*, Knotty Crane's-Bill; 3. *G. striatum*, Streaked Crane's-Bill; 4. *G. Sibericum*, Siberian Crane's-Bill; 5. *G. sanguineum*, Bloody Crane's-Bill; 6. *G. macrorhizum*, Long-rooted Crane's-Bill.

Other species may be cultivated.

The first has upright stems, nearly cylindrical, from eighteen inches to two and even three feet in height, below woolly, and having a few long shining hairs on them; joints large, commonly tinged with red: the leaves are soft, the younger ones silky, ribbed; the lower on long petioles in pairs, the upper solitary; lobes mostly five, unequally toothed, the lateral ones lobed: the lower leaves have frequently six or seven lobes, and the uppermost only three or four. The flowers are of a

blackish purple colour. It is a native of Switzerland, &c.

The second species is herbaceous, with smooth shining stems, swelled at the joints, having knobs like little bulbs at the origin of the branches and peduncles; whence the name: the flower-leaves are petioled, three-lobed, ovate-acuminate, serrate; the upper ones smaller, subsessile, the middle segment larger than the others. The flowers are of a purple colour. It is a native of Dauphiné, flowering in July and August.

The third has a perennial root, sending up many branching stalks a foot and half high: the leaves are light green; those on the lower part of the stalk have five lobes, and stand upon long foot-stalks; those on the upper part have but three lobes, sit closer to the stalks, and are sharply indented on the edges; they are gashed, and have a ferruginous or purplish brown spot at their base: the peduncles are long and slender: the petals obtuse, deeply indented at top, of a dull white, finely reticulated with many purple veins. It is a native of Italy, flowering in May and June.

The fourth species has also a perennial root: the stems are herbaceous, annual, diffusely dichotomous, jointed, almost round and smooth. At the divisions on each side is a lanceolate acuminate stipule: the leaves are opposite, five-parted, divided into unequally pinnatifid acute segments: the peduncles are longer than the leaves, from the axils, with two bracts at top: the calycine leaflets somewhat hirsute, with short awns: the petals are pale purplish, without any streaks, scarcely longer than the calyx, either quite entire or slightly emarginate. It is a native of Siberia, flowering in June.

The fifth has a perennial, somewhat woody root: the whole plant is set with white spreading hairs: the stems a foot or more in height, lax, spreading, branched, round, jointed, swelling at the joints: the leaves opposite, deeply lobed and cut, sometimes seven-parted, the segments linear, the upper surface rough, the lower hairy, the edge also is hairy and entire: the peduncles axillary, much longer than the leaves, hairy, with a joint and two small bracts more than half way down. Calycine leaflets oval, with membranaceous reddish edges, and terminated by a short red awn: the petals are obcordate, very large, pale red, with deeper veins, hairy at the base. The whole plant frequently turns red or purple after flowering. It is a native of many parts of Europe, flowering most part of the summer.

There are varieties, with short spreading stems and smaller leaves and flowers, with larger leaves deeply divided, and with variegated or striped flowers.

The sixth species has a perennial root, the thickness of a finger, becoming woody, dark purple on the outside, round, single, or branched, having many long, round, thickish fibres. Hence springs a bundle of leaves, and several almost upright stems, or rather scapes. These are all very soft and smooth, with a very short close down. Most of the leaves are large subpetate-seven-parted, on very long petioles; the lobes are oblong, a little narrowed towards the base, serrate-toothed; the edges tinged with pale red; the petiole round, strong, erect; as are also the scapes, which are somewhat higher than the leaves, silky-tomentose, quite simple, leafless, terminating in two peduncles, or else simply two-flowered; the flowers are large, elegant, deep red, or bright purple; and the whole plant, when rubbed, emits an agreeable odour. It is a native of Italy, flowering in May and June.

Culture.—All these plants may be increased either by sowing the seeds or parting the roots. In the first method the seeds should be sown in the autumn as soon as they are become perfectly ripe, either in pots, or a shady border, where the soil is light and fine. When the plants have a few inches growth, they may either be pricked out into other pots or beds at five or six inches distance, or be suffered to remain till the following autumn or spring, when they may be removed into other pots, or be set out where they are to remain, being occasionally supplied with water.

In the second method, the roots should not be too much divided, and be planted in the early part of the autumn, where the plants are to remain.

They are most of them of hardy growth, succeeding in most sorts of soils, requiring little culture, except that of being kept clean from weeds.

They are all proper for affording variety in the borders and other parts of ornamented grounds, and the potted sorts in collections about the house.

GEUM, a genus containing plants of the herbaceous perennial kind.

It belongs to the class and order *Icosandria Polygynia*, and ranks in the natural order of *Senticosæ*.

The characters are: that the calyx is a one-leaved perianthium, ten-cleft, uprightish: segments alternately very small, sharp: the corolla has five petals, rounded: claws the length of the calyx, narrow, inserted into the calyx: the stamina have numerous filaments, subulate, length of the calyx, into which they are inserted: anthers short, broadish, blunt: the pistillum has numerous germs, collected into a head: styles inserted into the side of the germ, (terminating

hairy, long: stigmas simple: there is no pericarpium: common receptacle of the seeds oblong, (columnar,) hirsute, placed on the reflex calyx: the seeds numerous, compressed, hispid, awned, with a long style.

The species are: 1. *G. Virginianum*, American Avens; 2. *G. montanum*, Mountain Avens; 3. *G. rivale*, Water Avens.

The first has the stem a foot and half or two feet high, branching at top into small peduncles, each terminated by a small white flower. It is a native of North America, flowering in July and August.

In the second species, the root-leaves are in a tuft, on petioles of different lengths; these are hairy, and have several pairs of leaflets on them; the lowest very small, the succeeding ones gradually larger, and the pair immediately under the great terminating leaflet much bigger than any of the rest: the extreme leaflet is two or three inches in length and breadth, obscurely lobed, gash-serrate, and veined: the leaves of the stem sessile, solitary, alternate, trifid: the pinnae smaller and more crowded than in the others, sessile and gash-serrate: the stem is unbranched, from a span to a foot and half in height: the flowers are large, solitary, spreading, upright, of a yellow colour. It is a native of France, flowering in June and July.

There is a variety, with large golden flowers.

The third has a creeping, reddish, astringent, aromatic root, smelling like cloves: the stem a foot high, upright, round and branched, bending at top, but becoming erect as the fruit ripens: the leaves are lyrate, jagged, gash-serrate and hirsute: stipules undivided or jagged: the peduncles purplish, hirsute with hairs terminating in a red globule; becoming less bent as the seeds ripen. It is a native of most countries of Europe; flowering from May till the autumn.

It varies with yellow flowers, and with double flowers.

Culture.—All these plants are capable of being increased, both by seeds and parting the roots.

The seeds should be sown in the early autumn in the situations where the plants are to grow, or in a shady situation, to be removed when of a proper growth.

The partings of the roots may be planted out where the plants are to remain in the early part of the autumn, when the weather is mild, and rather moist.

These plants are hardy, and require little cultivation afterwards.

They afford ornament and variety in the borders and clumps of pleasure-grounds among other flowering plants.

GILLIFLOWER. See DIANTHUS.

GLADIOLUS, a genus comprising plants of the tuberous-rooted flowery perennial kind.

It belongs to the class and order *Triandria Monogynia*, and ranks in the natural order of *Ensatae*.

The characters are: that the calyx is a spathe, two-valved, inferior; shorter than the corolla: valves oblong, permanent; the outer one larger, inclosing the inner: the corolla is one-petalled, superior: tube cylindric, bent: border somewhat bell-shaped, six-parted; segments oblong, from erect-patulous, the uppermost and lowest lateral either without or within: the stamina have three filaments, inserted into the orifice of the tube, filiform, shorter than the corolla: anthers ovate, incumbent: the pistillum is an inferior germ, triangular: style filiform: stigmas three, rolled back and spreading, blunt, villose: the pericarpium is an ovate capsule, three-cornered, blunt, three-celled, three-valved: the seeds very many and smooth.

The species are: 1. *G. communis*, Common Sword-Lily, or Corn-Flag; 2. *G. imbricatus*, Imbricated-flowered Gladiolus; 3. *G. tristis*, Square-stalked Gladiolus; 4. *G. angustus*, Narrow-leaved Gladiolus; 5. *G. cardinalis*, Superb Scarlet Gladiolus.

The first has a yellowish, round, compressed root covered with a brown furrowed skin; hence spring two sword-shaped leaves, embracing each other at the base, and between them rises the flower-stalk, growing near two feet high, having one or two narrow leaves embracing it like a sheath, and terminated by five or six purple flowers, one above another at some distance, ranged on the same side of the stalk: the spathe covers the flower-bud before it expands, but splits open lengthwise when it opens, and shrivels up to a dry skin, remaining about the seed-vessel till the seeds are ripe.

It is divided by Mr. Miller into three species, as the common sort described above, with the flowers disposed on one side the stalk, varying with white and flesh-coloured flowers, called *Italian Corn-flag*; the Italian, with flowers on each side the stalk, of which there is a variety with white flowers, named *French Corn-flag*; and the Great Corn-flag of Byzantium, which has larger roots, but of the same form; the leaves are much broader and larger, with deeper channels: the flower-stalks rise higher, the flowers are much larger, of a deeper red colour, and the sheaths longer. This is the sort mostly cultivated, which makes a fine appearance when in flower, and the roots do not increase so as to be inconvenient.

Besides these, according to some, there are three other varieties; the Blush, the White, and the Small Purple.

In the second species the leaves are sword-

shaped, and the flowers small, being all directed one way, and imbricate. It is a native of Russia.

In the third come out two or three narrow leaves from the root, a foot and half long, having a longitudinal furrow in the middle, and ending in acute points; they are of a deep green, and stand erect. Between these arises a slender taper stalk, about the same length as the leaves, having one or two short acute-pointed leaves on the lower part, embracing the stalk at their base: the flowers are alternate, distant: the tube of the corolla curved downward, and not so long as in most of the other sorts; segments acute, and nearly equal; pale yellow or sulphur colour. It is a native of the Cape, flowering in the end of May.

The flowers vary much with different shades of white and green, yellow, flesh-coloured, blue, purple and violet. It is commonly said to produce only two flowers on a stem, but there are frequently more, which generally give forth a most agreeable fragrance in their expansion.

The fourth species has a simple scape, or but little branched, sheathed, round, striated, smooth, flexuose-erect, a foot high: the leaves are from long sheaths, ensiform, marked with white elevated streaks, entire, smooth, shorter than the scape; the upper ones gradually smaller; the flowers all on the same side, ascending, on one or two spikes, a hand in length: the rachis angular, flexuose, twisted, smooth: the spathe the length of the tube of the corolla, shorter than the branches, green: the segments of the border of the corolla usually waved.

In the fifth the flowers are fine scarlet, with large white somewhat rhomboidal spots on several of the lowermost divisions of the corolla: strong plants will throw up a stem three or four feet high, dividing at top into several branches. It flowers here in July and August; and is probably a native of the Cape.

Culture.—The first sort and varieties are capable of being readily increased, by planting the off-sets from the old roots in the beginning of the autumn, in the places where the plants are to remain.

The other sorts may likewise be raised in the same way as well as by seeds. These should be planted in a warm border, and be protected in the winter by glasses or some other means, when there is a necessity for it.

When raised from seed it should be sown towards the end of August, in pots filled with light earth, placing them in a shady situation at first, but afterwards where they may be exposed to the sun, being protected during the winter in a hot-bed frame, free air being admitted when the weather is mild. In the spring the pots should be removed to a shady situation, with

only the morning sun. When the stems decay, the roots should be taken up and kept in sand in a dry place, till the time of planting. In the second year's planting, they should be put in separate small pots.

The old roots may be taken up every two or three years, to have the off-sets taken off from them.

They produce a fine effect and variety in the flower borders and other parts among other flowering plants.

GLASS CASE, a light sort of erection formed with glass sashes, in proper frame-work, mostly upright in the front part and ends, but sloping at top from a back wall, or other convenient building, to the fore part; the front, top, and both ends being of glass-work. The situation for this purpose should face the south, in order to have the full influence of the sun. Constructions of this nature are useful for protecting many sorts of curious tenderish plants in winter, which want it only occasionally from severe frost, and other similar causes.

Buildings of this kind may be constructed occasionally, either against some ready-built south wall, which serves for the back, all the other parts forward being wood-work and glass; or detached in a similar situation, so as that the whole front may stand to the south, the back being formed of brick-work, &c. or of wood double planked; but the former is preferable; the whole being generally ranged lengthways, nearly east and west.

The dimensions may be from five or six, to eight or ten feet in width, by ten, fifteen, or twenty feet in length or more, as may be required; and from six or eight, to ten feet high behind, by five or six, to seven or eight in the front, both ends in proportion with the top, sloping gradually, as just noticed, from the back, having an entrance or door in front, or at one end. The glass-work should be made to slide.

Sometimes fire-flues are carried along the back and front internally, proceeding from an external furnace, for occasional fire-heat in winter, which render them more convenient and useful for different purposes.

These Cases, as mentioned above, are used as preservatory departments, in which to winter many sorts of curious exotics, of the hardier green-house kinds, which only want protection from severe cold, as well as many choice kinds of the open ground which are rather tenderish in their minor growth, or any other particular or curious hardy plants, whether flowers, shrubs, or young trees, especially the choice evergreen kinds, which require effectual protection from the ravages of rigorous frosts or cutting winds in winter or early spring; and at the same time, in mild open weather, to

enjoy the full air by opening the glasses; all which, being in pots, can be readily placed in this preservatory at the approach of severe weather, and be thus kept in good condition till settled weather in spring, &c. then removed into the full air: in summer and autumn, when unoccupied in this way, these Cases may be of utility to place some kinds of curious tender plants in when in flower for seeding, to guard them from heavy or incessant rain or cold night dews in autumn, which in many sorts retard, or sometimes wholly frustrate their production of good seed, as in some sorts of curious tender Annuals, particularly the fine Double Balsams, Cock's-Combs, Tricolors, Double Stramoniums, Diamond Ficoides, and various others.

They are also capable of being used in spring and the early part of summer, as April, May, and June, as a kind of drawing-frames, for some particular sorts of curious Annuals, to bring them to a tall growth, such as the Large or Giant Cock's-Combs, Tricolors, Double-Stramoniums, Double-striped Balsams, Egg-plants, &c. the plants being first raised in hot-beds under garden-frames, till of twelve or fifteen inches growth, then a hot-bed made in the Glass-Case, earthed at top, and the plants in pots singly plunged into the earth of it; the glasses in these cases being shut close, only a necessary admission of fresh air being given every day, by which they run up to a tall stature, in the best perfection of strength for flowering. See ANNUAL PLANTS.

These glass cases are also sometimes made use of as a kind of appurtenances to hot-houses or stoves detached from them, having, as observed above, internal flues for fire-heat when necessary, serving as preservatories for many sorts of exotics, which are tenderer than common green-house plants, but do not require the constant full heat of the more tender hot-house kinds, but only the assistance of moderate fire-heat in winter, in cold nights, or when very damp, cloudy, foggy weather and severe frosts prevail. They are sometimes used in the business of forcing different kinds of flowering plants and esculents, either by means of an internal bark-bed, or flues for fire-heat.

When intended for this purpose, it is convenient to have both an internal pit for a bark-bed, and flues for fire-heat, in order to use either separately, or sometimes both, as it may be found necessary.

GLASTONBURY THORN. See *MESPILUS*.

GLEDITSIA, a genus containing a plant of the deciduous tree kind.

It belongs to the class and order *Polygamia Dioecia*, and ranks in the natural order of *Lomentaceae*.

The characters are: that the male has a long, compact, cylindric ament: the calyx is a perianthium proper, three-leaved, (three-cleft,) leaflets patulous, small, acute: the corolla has three roundish petals, sessile, patulous, like the calyx: nectary turbinate, with the other parts of the fructification growing to the mouth: the stamina have six filiform filaments, longer than the corolla; anthers incumbent, oblong, compressed, twin: hermaphrodite in the same ament with the males, usually terminating: the calyx is a four-cleft perianthium, otherwise as in the male: the corolla has four petals, otherwise as in the male: nectary as in the male: the stamina as in the males: the pistillum, pericarpium, and seed as in the female: female a lax ament, on a distinct plant: the calyx is a perianthium proper, as in the male, but five-leaved (five-cleft): the corolla has five petals, long, sharp, from upright spreading: nectaries two, short, like filaments: the pistillum is a broad germ, flattened, longer than the corolla: style short, reflex: stigma thick, the length of the style, along which it grows, pubescent at top: the pericarpium is a very large broad legume, extremely flattened, divided by several transverse partitions, and filled with pulp: the seeds solitary, roundish, hard, shining.

The species is *G. triacanthos*, Three-thorned Acacia.

It is a tree common in most parts of North America, where it is known by the name of Honey Locust. It rises with an erect trunk to the height of thirty or forty feet, and is armed with long spines, three or four inches long, which have two or three smaller ones coming out from the side, and are frequently produced in clusters at the knots of the stem. The leaves are bipinnate, composed of ten pairs of leaflets, of a lucid green colour, and sessile. The flowers come out from the side of the young branches, but, being of a herbaceous colour, have little appearance.

In this climate the leaves seldom come out till June, and the flowers not till the end of July; the tree does not produce flowers till it is of a large size.

There are varieties with fewer spines, and the leaves smaller, the pods oval; with but one seed; and with stronger spines.

Culture.—These trees are capable of being increased by sowing the seeds obtained from America, in a bed of light earth in the early spring, water being occasionally given when the weather is dry. But it is a more expeditious practice to sow them in pots, and plunge them in a moderate hot-bed. They should be kept clean during the first summer, and in the win-

ter be protected from sharp frosts, especially those plants that are in pots. In the following spring the young plants may be most of them removed into nursery-rows at a foot or eighteen inches distant, with eight or ten inches in the rows. The small ones that remain may be put out in the following autumn or spring. They should remain in this situation till they have had two or three years growth, when they may be planted where they are to remain any time in the later part of the spring.

They succeed best in light deep soils in sheltered situations.

These are all very ornamental trees, being well suited to plantations and large shrubbery parts, and when planted alone in large openings or lawns kept in grass they produce a fine effect, but have the disadvantage of putting forth their leaves late.

GLOBE-AMARANTH. See *GOMPHRENA*.

GLOBE-FLOWER. See *TROLLIUS*.

GLOBE-THISTLE. See *ECHINOPS*.

GLOBULARIA, a genus comprising plants of the herbaceous flowery perennial kind.

It belongs to the class and order *Tetrandria Monogynia*, and ranks in the natural order of *Aggregatae*.

The characters are: that the calyx is a common perianthium, imbricate, with scales the length of the disk and equal: proper one-leaved, tubular, five-cleft, sharp, permanent (four- or five-toothed; the teeth bristle-shaped and acuminate): corolla is universal, nearly equal: proper monopetalous, tubular at the base: border five-parted: upper lip very narrow, two-parted, shorter: lower of three larger, equal segments: the stamina have four filaments, simple, the length of the corollule: anthers distinct, incumbent: the pistillum is an ovate superior germ: style simple, the length of the stamens: stigma obtuse: there is no pericarpium: proper calyx converging, inclosing the seed: the seeds are solitary and ovate: the receptacle is common, oblong, separated by chaffs.

The species chiefly cultivated are: 1. *G. Alypum*, Three-tooth-leaved Globularia; 2. *G. vulgaris*, Common Globularia, or Blue Daisy.

There are other species that may be cultivated.

The first has a hard woody stem, about two feet high, with many woody branches, beset with leaves like those of the myrtle. The flowers are produced on the tops of the branches in a ball, and are of a blue colour. It is a native of the south of Europe, flowering from August to November.

This shrub is said to possess a violent purging quality.

The second species has the stem slender, upright, covered with leaves, from an inch and half to six inches in height, and sometimes more, somewhat angular, very simple, smooth, one-flowered. The root-leaves are numerous, like those of the daisy, but thicker, petioled, placed in a ring, ovate, obtuse, quite entire, emarginate, the nerve produced into a small awn or point: the stem-leaves alternate, nearer to sessile, smaller, three-toothed, four lines broad, from an inch to an inch and a half in length, all smooth, and of a bright green. The flowers are in a globular head, and of a blue colour. It is a native of many parts of Europe, flowering in May and June.

It varies with a white flower, and with a leafless stalk or stem.

Culture.—The first species may be increased by planting cuttings of the young branches in April, just before they begin to shoot, in pots of light fresh mould, plunging them in a very moderate hot-bed, giving them due water and shade till they have stricken root. After this they should be removed from the bed, and gradually hardened to the open air. The plants should afterwards be protected during the winter.

The second sort is readily increased by parting the roots as in the Common Daisy, planting them out in the early part of the autumn in moist shady situations. They succeed best in such loamy soils as are rather moist.

These plants are ornamental, the first sort among potted plants, the latter in the fronts of the more moist and shady borders or clumps of pleasure-grounds.

GLORIOSA, a genus containing a plant of the herbaceous flowering perennial kind.

It belongs to the class and order *Hexandria Monogynia*, and ranks in the natural order of *Sarmentaceæ*.

The characters are: that there is no calyx: the corolla has six petals, oblong-lanceolate, waved, very long, woolly reflex: the stamina have six subulate filaments, shorter than the corolla, from straight patulous: anthers incumbent: the pistillum is a globular germ: style filiform, longer than the stamens, inclined: stigma triple, obtuse: the pericarpium is a superior capsule, oval, three-lobed, three-celled, three-valved: the seeds several, globular, berried, in two rows.

The species is *G. superba*, Superb Lily.

It has a long fleshy root of a whitish colour, and a nauseous bitter taste, from the middle of which arises a round weak stem, requiring support, and with that growing to the height of eight or ten feet. The leaves are smooth, about eight inches long, and one inch and a half

broad at the base, growing narrower till within two inches of the end, which runs out in a narrow point, and ends in a tendril: the flowers are at the upper part of the stem, from the side, on slender peduncles, hanging down, at first of a herbaceous colour, but changing to a beautiful flame-colour. It is a native of Guinea, flowering in June and July. The roots and other parts are poisonous.

Culture.—This plant is capable of being increased by planting the offsets from the old roots, either in the autumn after the stems decay, or in the early spring before they shoot, in pots filled with light earth, plunging them in the bark-bed of the stove. The old roots, when taken out of the ground, should be preserved in dry sand during the winter in the stove, or in a dry warm room. It is the practice of some to let the roots remain during the winter in the mould, keeping the pots in the tan-bed; planting out the offsets early in the spring. In either way they should have very little water.

When the stems appear, they should be supported by sticks, and in hot dry weather a little water be sparingly given, as there may be occasion.

The pots in which they are planted should be small, that they may be confined and put forth stronger stems. Twopenny pots will be large enough for roots of the greatest size.

These plants are highly ornamental on account of their beautiful flowers among others of the stove kind.

GLOXINIA, a genus comprising a plant of the herbaceous flowery perennial kind.

It belongs to the class and order *Didynamia Angiospermia*, and ranks in the natural order of *Personatæ*.

The characters are: that the calyx is a superior perianthium, five-leaved: leaflets equal, lanceolate, serrulate at the tip, the three upper ones nerved, the two lower bent down with the nectary, permanent: the corolla is monopetalous, irregularly campanulate: tube scarcely any: border oblique, five-cleft, segments roundish, the four upper spreading and entire, the lowest straight, concave, toothed: the stamina have four filaments, with the rudiment of a fifth, two scarcely shorter, inserted into the receptacle, fastened to the lower margin of the corolla, sickled, pubescent, converging laterally above: anthers ovate, two celled, peltate, united within the opening of the corolla: the pistillum is an inferior germ, turbinate, striated: style filiform, the length of the stamens: stigma capitate, the length of the anthers: the pericarpium is a one-celled capsule (or half-celled): receptacles two, opposite, two-parted, fastened to

the sides of the capsule by the partition: the seeds very numerous, inserted into the receptacles.

The species is *G. maculata*, Spotted Gloxinia.

It has a perennial thick fleshy root, divided into knots, which are scaly. The stems are several, about a foot high, thick, succulent, and purplish. The leaves are oblong, thick, sessile, serrate, rough on their upper side, where they are of a dark green, but their under side is purplish. The stems are terminated by short spikes of blue flowers; or rather an erect raceme, leafy or bracted; in which the flowers are axillary, solitary, peduncled, bright blue, and sweet-scented. It is a native of South America.

Culture.—These plants may be readily increased by planting the divided roots in the early spring, in middle-sized pots, filled with good mould, which must be plunged into a fresh tan-bed. After the plants are up they must be often refreshed with a little water, and when the weather is hot have air freely admitted.

They may also be raised from cuttings of the young shoots, planted and managed in the same way in the summer season.

They must be constantly kept in the stove in an open situation, and never transplanted when in leaf, as by that means they are prevented from flowering.

They afford variety in collections of the stove kind.

GLYCINE, a genus containing plants of the shrubby climbing kind.

It belongs to the class and order *Diadelphica Decandria*, and ranks in the natural order of *Papilionaceæ*.

The characters are: that the calyx is a one-leaved, compressed perianthium: mouth two-lipped: upper lip emarginate, obtuse: lower longer, trifid, acute: the middle tooth more produced: the corolla is papilionaceous: banner obcordate, the sides bent down, the back gibbous, the tip emarginate, straight, repelled from the keel: wings oblong, towards the tip ovate, small, bent downwards: keel linear, sickle-shaped, bent upwards, at the tip pressing the banner upwards, obtuse, towards the tip broader: the stamina have diadelphous filaments (simple and nine-cleft), only a little divided at the tip, rolled back: anthers simple: the pistillum is an oblong germ: style cylindric, rolled back in a spiral: stigma obtuse: pericarpium an oblong legume: the seeds kidney-form.

The species are: 1. *G. frutescens*, Shrubby Glycine, or Carolina Kidney-bean Tree; 2. *G.*

bimaculata, Two-spotted Glycine; 3. *G. rubicunda*, Reddish-flowered Glycine; 4. *G. coriacea*, Scarlet Glycine.

The first has woody stalks, which twist themselves together, and also twine round any trees that grow near, and will rise to the height of fifteen feet or more. The leaves are in shape somewhat like those of the ash-tree, but have a greater number of leaflets. The flowers are produced in clusters from the axils, and are of a purple colour. They are succeeded by long cylindrical legumes, shaped like those of the Scarlet Kidney-bean, containing several seeds, which are never perfected in this climate. It flowers from June to September.

The second species rises with a twining shrubby stalk to the height of six or eight feet and more; multiplying greatly by age, becoming loaded with a profusion of purple flowers growing in racemes; the richness of the corolla is enlivened by two green spots at the base of the banner. For the most part the flowers go off in this climate without producing any seed-vessels. It begins to flower in February, and continues during the summer. It is a native of Botany Bay.

The third has a shrubby, slender, twining stem, five or six feet high and more, red, branched, leafy. The leaves ternate, on petioles from an inch to two inches in length, channelled above, round underneath: leaflets ovate or elliptic, quite entire, the two side-ones on very short petioles, the end-one on a petiole half an inch in length, bending and swelling immediately under the leaflet, and having there a pair of deciduous stipules. Almost the whole plant is covered with hairs pressed close.

The flowers are of a purplish-scarlet colour. It is a native of New South Wales, flowering from April to June.

The fourth is a shrubby climbing plant, growing to the height of many feet, if supported, and producing a great number of flowers on its pendent branches. The leaflets nearly round, and in the older ones especially curled at the edges. The flowers for the most part in pairs, of a glowing scarlet colour, at the base of the keel somewhat inclined to purple; the bottom of the banner is decorated with a large yellow spot, verging to green. It flowers from April to June, and is a native of New South Wales.

Culture.—The first sort is increased by laying down the young branches in the early autumn. When well rooted in the following autumn, they may be taken off and planted where they are to remain, or in nursery-rows, being watered when the weather is hot, and the roots

protected in the winter by some sort of strawy material.

They succeed best in dry warm light soils.

The other sorts may be raised by sowing the seeds, when they can be obtained from abroad or produced here, in pots of light earth, in the early spring, being afterwards removed into other pots, and placed in the green-house or Cape stove. Mr. Curtis, however, suggests that the two last may succeed in the open air, when planted out in warm sheltered situations, and protected in the winter season.

They are all ornamental in their flowery climbing nature; the first in the open ground, and the latter in the green-house and stove collections.

GLYCYRRHIZA, a genus furnishing a plant of the herbaceous perennial kind.

It belongs to the class and order *Diadelphia Decandria*, and ranks in the natural order of *Papilionaceæ*.

The characters are: that the calyx is a one-leaved tubular perianthium, two-lipped, permanent: upper lip three-parted: the lateral segments linear, the middle one broader, bifid: lower entirely simple, linear: the corolla is papilionaceous: banner ovate-lanceolate, straight, longer: wings oblong, very like the keel, but a little larger: keel two-petalled, acute, with a claw the length of the calyx: the stamina have diadelphous filaments (simple and nine-cleft), straight: anthers simple, roundish: the pistillum is a germ shorter than the calyx: style subulate, the length of the stamens: stigma obtuse, ascending: the pericarpium is an ovate or oblong legume, compressed, acute, one-celled: the seeds very few, and kidney-form: calyx two-lipped: upper lip three-parted, lower undivided: legume ovate, compressed.

The species cultivated is *G. glabra*, Common Liquorice.

It has the roots running very deep into the ground, and creeping to a considerable distance, especially where they stand long unremoved. From these arise strong herbaceous stalks, four or five feet high. The leaves are composed of four or five pairs of ovate leaflets, terminated by an odd one: these and the stalks are clammy, and of a dark green. The flowers are in axillary spikes, standing erect, and of a pale blue colour. The pods are short, containing two or three seeds.

This plant is cultivated for its roots, which are useful for different purposes.

Culture.—A light sandy soil is the most adapted to the growth of this sort of crops, as its goodness consists in the length of the roots. The ground in which it is intended to be planted should be well dug and dunged the year be-

fore planting, that it may have become perfectly mellow, and the dung well rotted, and mixed with the earth, otherwise it will be apt to stop the roots from running down and being properly supported; and immediately before planting it should be well dug again to the depth of three spades, and be laid very light.

When thus prepared, fresh plants taken from the sides or heads of the old roots should be provided, care being taken that they have each a good bud or eye, being about ten inches long, and perfectly sound.

The operation of planting them should be performed about the middle of March, which is done in this manner:—a line is first set across the ground, then with a long dibble made on purpose the shoots or cuttings are put in, so that the whole plants may be set into the ground, with the heads about an inch under the surface, in a straight line, about a foot asunder in the rows, and a foot and half or two feet distance row from row.

When the whole spot of ground has been thus planted, a thin crop of onions may be sown over the land. These must be kept perfectly clean by the hoe, care being taken not to cut off the top shoots of the liquorice plants, as it would greatly injure them. All the onions which grow near the heads of the liquorice should also be removed. In October, the shoots of the liquorice should be removed, and a little very rotten dung spread upon the surface.

In the following spring, about March, the ground should be slightly dug between the rows of liquorice, burying the remaining part of the dung, being very careful not to cut the roots.

During the summer they must be kept quite clean by occasional hoeing. The same operations must be annually performed, so as to keep the ground and plants in perfect order.

These plants must remain three years from the time of planting, when they will be fit to take up for use, which should be done when the stalks are perfectly decayed: as, when taken up too soon, the roots shrink greatly, and lose in weight.

In taking up the roots the ground is trenched over row after row to the full depth, and the young shoots taken from the old roots cut into sets for new plantations; which should be made annually, in order to keep a constant succession of roots fit for being taken up.

The great art in this culture is to have the earth well trenched to a proper depth, to have good sets, and to keep the ground afterwards quite clean by hoeing.

GNAPHALIUM, a genus affording plants of the herbaceous and under shrubby kinds.

It belongs to the class and order *Syngenesia Polygamia Superflua*, and ranks in the natural order of *Compositæ Discoideæ*.

The characters are: that the calyx is common, rounded, imbricate, with the marginal scales rounded, scarious, coloured: the corolla compound: corollets hermaphrodite, tubular, with apetalous females sometimes intermixt: hermaphrodites funnel-form, with a five-cleft, reflex border: the stamina (in the hermaphrodites) have five capillary filaments, very short: anther cylindric, tubulous: the pistillum is an ovate germ: style filiform, the length of the stamens; stigma bifid, in the females, reflex: there is no pericarpium: calyx permanent, shining: the seeds solitary, oblong, small, crowned with a capillary or feathered down: the receptacle is naked.

The species are: 1. *G. arboreum*, Tree Everlasting; 2. *G. ignescens*, Red-flowered Everlasting; 3. *G. orientale*, Eastern Everlasting, or Immortal Flower; 4. *G. odoratissimum*, Sweet-scented Everlasting, or Eternal Flower; 5. *G. margaritaceum*, American Everlasting, or Eternal Flower; 6. *G. plantagineum*, Plantain-leaved Everlasting; 7. *G. stuechas*, Common Shrubby Everlasting, or Stœchas.

The first is a shrub the height of a man, determinately branched. The leaves resembling those of rosemary, crowded, strict, acute, naked, underneath tomentose, as are also the branches; with smaller leaves alternate, remote. The flowers are of a dusky white colour. It flowers most part of the year.

The second species has the stem and leaves woolly; the former a foot high, sending out a few side-branches, terminated by a compound corymb of flowers, the heads of which are small, of a gold colour, changing to red as they fade or decline. Its native situation is not known.

The third has the stem seldom rising more than three or four inches high, and putting out many heads. The leaves are narrow, woolly on both sides, and coming out without order. The flower-stems eight or ten inches high, with narrow hoary leaves all the way, terminated by a compound corymb of bright yellow flowers in large heads, coming out in May, and continuing in succession most part of the summer. It has been long in Portugal.

It is improperly called Eastern Everlasting, according to Martyn, as it is supposed to be a native of Africa.

There is a shrubby variety with narrow leaves, which differs from the other in rising with stalks four or five feet high, dividing into many branches, having long narrow leaves placed alternately; the corymb is loose, with the

flowers on long pedicles, and with broad leaves.

The fourth species has the lower leaves oblong and blunt. The stems about three feet high, dividing into many irregular branches, on which are oblong blunt leaves, hoary on their under side, but of a dark green above and decurrent. The stems are terminated by a compound corymb of flowers, closely joined together, of a bright gold colour, but small, and changing to a darker colour as they fade. It is a native of the Cape.

The fifth has a perennial root, creeping, and spreading far, so as to become a troublesome weed. The stalks extremely downy and white. The leaves are numerous, long, sessile, growing without order round the stem, entire at the edges, dark green, naked above, beneath covered with a thick down, and whitish. The flowering branches form a broad flat bunch: each branch contains numerous crowded heads, on short branched, downy peduncles, but the middle ones sessile. It is a native of North America.

The sixth is perennial. From the main stalk come out runners, which take root in the ground. The stem-leaves are narrower, woolly, alternate. The flowers in a terminating corymb, white and small, appearing in June and July. It is a native of North America.

The seventh has the stem about three feet high, with long slender irregular branches, the lower ones having blunt leaves two inches and a half long, and an eighth of an inch broad at the end; those on the flower-stalks are very narrow, and end in acute points; the whole plant being very woolly. The flowers terminating in a compound corymb, at first silvery, but turning to a yellow sulphur-colour. When gathered before the flowers are much opened, Martyn says, the heads will continue in beauty many years, if kept from air and dust. It is a native of Germany.

Culture.—The first four sorts may be increased by slips from the heads, or cuttings, by planting them in pots of light earth, in the spring or summer months, and plunging them in a moderate hot-bed, refreshing them often with water. When they have taken full root they may be removed into separate pots, and be placed among other plants of the hardy exotic sort. They require the protection of a frame in the winter season.

The seventh species may be increased in the same manner, being planted at once where it is to remain, in a shady sheltered border or other place.

The fifth and sixth sorts may be easily raised by dividing and planting their creeping roots

where they are to grow, either in the autumn or spring.

These three last are sufficiently hardy to stand the open air in warm situations.

They are all ornamental plants, the former in the green-house collection, and the latter in the open ground.

GOLDEN-ROD. See *SOLIDAGO*.

GOLDEN-TREE. See *BOSEA*.

GOLDILOCKS. See *CHRYSOCEMA* and *GNAPHALIUM*.

GOMPHRENA, a genus containing a plant of the flowery annual kind.

It belongs to the class and order *Pentandria Digynia*, and ranks in the natural order of *Amaranthi*.

The characters are: that the calyx is a coloured perianthium; outer three-leaved: leaflets two, converging, keeled: the corolla five-petaled, upright: petal subulate, permanent, rude, villose: nectary a cylindric tube, the length of the corolla; with a five-toothed, patulous mouth: the stamina have five filaments, scarcely observable, within the mouth of the nectary: anthers upright, closing the mouth of the nectary: the pistillum is an ovate germ, with a point: style cloven half way, filiform: stigmas simple, the length of the stamens: the pericarpium a capsule roundish, circumcised: the seed single, large, roundish, with an oblique tip.

The species is *G. globosa*, Annual Globe Aramanth.

It is an annual plant, rising with an upright branching stalk, about two feet high: the leaves are opposite, sessile, quite entire, hispid: branches and peduncles also opposite; the latter axillary, long and naked, except that there are two short leaves close under each head of flowers. These heads at their first appearance are globular, but as they increase in size become oval. It is a native of India.

Martyn observes that the flowering heads are beautiful, and, if gathered before they are too far advanced, retain their beauty several years.

There are varieties with fine bright purple heads, with white or silvery heads, which never alter from seeds, with mixed colours, with purple and with white heads, which two last are much smaller and rounder than the others: the plants also grow much larger, and spread more into branches, and are later before they flower;—these are called Bachelors' Buttons in America.

Culture.—These plants may be raised by sow-

ing the seeds annually in pots of light fresh mould in the early spring months, and plunging them in the bark hot-bed. When the plants are up, they should be watered often with care; and, after they have attained some growth, be removed with balls about their roots into other pots, and replunged into the hot-bed. When they have had some growth in this situation, they should be removed into a deep frame, being placed in a fresh hot-bed, to bring them up tall.

They should here be often refreshed with water, and have air admitted freely as the summer advances, till they are capable of bearing it without injury; when about August they may be set out during the day time, being protected in the night, and from wet weather. At this period they should be watered three or four times a week.

They are highly ornamental plants for the principal situations about the house, in assemblage with other potted plants.

GOOSEBERRY. See *RIBES*.

GOOSE-FOOT. See *CHENOPODIUM*.

GORDONIA, a genus containing plants of the shrubby evergreen exotic kind.

It belongs to the class and order *Monadelphia Polyandria*, (*Polyandria Monogynia*), and ranks in the natural order of *Columniferae*.

The characters are: that the calyx is a perianthium (double: outer four-leaved, deciduous; inner five-leaved: leaflets roundish, concave (ciliate) permanent: the corolla has five petals, obovate, concave, large, united at the base (one of them ciliate): the stamina have numerous filiform filaments, coalescing at the base into an obtuse body (campanulate, with a five-cleft border): anthers oval, upright: the pistillum is an ovate germ: style short, five-cornered (cylindric): stigmas five, sharp, horizontal: (stigma five-cornered): the pericarpium is an ovate capsule, ovate, sharp, five-celled: cells bifid half way, five-valved: the seeds two, with a leafy wing on one side, in two rows in each cell.

The species cultivated are: 1. *G. lasianthus*, Smooth Loblolly Bay; 2. *G. pubescens*, Pubescent Loblolly Bay; 3. *G. Franklini*, Carolina Gordonia.

In the first, the stem is five or six feet high, and branched: the leaves four inches long, and one inch and a half broad in the middle, slightly indented on their edges, and of a thick consistence: the flowers axillary, on very long peduncles; of a yellowish white colour. Some describe it as a tall straight tree, with a regular pyramidal head. It is a native of North America, flowering in August and September.

In the second species, the branches are sub-

pubescent: the leaves as in the first, but with the lower surface very softly tomentose: the flowers axillary, solitary, sessile towards the tops of the branches: the leaflets of the outer calyx subovate, acuminate at the tip, tomentose, and of a white colour; also those of the inner. It is a native of South Carolina, flowering in September.

The third is a beautiful tree-like shrub, which rises with an erect trunk to the height of about twenty feet, with alternate branches: the leaves are oblong, narrowed towards the base, serrate, alternate, sessile or subsessile: flowers towards the extremity of the branches, solitary, sitting close in the bosom of the leaves, often five inches in diameter when fully expanded: the petals snow-white, the lower one hollow, formed like a cap or helmet, entirely including the other four, until the moment of expansion; its exterior surface is covered with a short silky hair: the borders of the petals are curled or plaited. It is a native of South Carolina.

The flowers have the fragrance of the China Orange.

Culture.—These plants, from their being aquatics, are not raised or preserved without great difficulty. It is effected by planting cuttings of the young shoots, or laying them down in the spring season in pots of moist earth, plunging them in the hot-bed, and supplying them freely with water. They are very ornamental stove plants.

GORTERIA, a genus containing plants of the herbaceous shrubby sort for the green-house.

It belongs to the class and order *Syngenesia Polygamia Frustranea*, and ranks in the natural order of *Compositæ Capitatae*.

The characters are: that the calyx is common one-leaved, imbricate with spiny scales, the inner ones gradually longer, straight, bristle-shaped, ridged: the corolla compound radiate: corollets hermaphrodite, several in the disk: female fewer in the ray: proper of the hermaphrodite funnel-form, five-cleft; of the female ligulate, lanceolate: the stamina in the hermaphrodites have five short filaments: anther cylindric, tubular: the pistillum of the hermaphrodite is a villose germ: style filiform, the length of the corollet; stigma bifid: of the females, germ obsolete: style none: stigma none: the pericarpium an unchanged, deciduous calyx: the seeds in the hermaphrodites, solitary, roundish; down simple (woolly): in the females, none: receptacle naked (not so in all the species).

The species cultivated are: 1. *G. rigens*, Great-flowered Gorteria; 2. *G. fruticosa*, Shrubby Gorteria.

The first is a low spreading plant, with woody stalks six or eight inches long, trailing on the

ground, having two or three side-branches, each terminating in a close head of leaves, which are narrow, green on their upper, but silvery on their under surface, and cut into three or five segments at the end. The peduncles which arise from these heads are six inches long, naked, and support one large orange-coloured flower: each floret in the ray has a dark mark towards the base, with white intermixed.

Martyn observes, that the green-house can scarcely boast a more showy plant: the flowers, when expanded by the heat of the sun (and it is only when the sun shines on them that they are fully expanded), exhibit an unrivalled brilliancy of appearance. It flowers in May and June.

The second species has a slender stem, three feet high, sending out a few weak branches, which are tomentose and white: the leaves are, like those of Privet, alternate, sharp, petioled, having six or seven serratures bristly at the end: the flowers terminating, subsolitary, peduncled, the peduncle longer than the flower, of a golden yellow colour. It flowers in August and September.

Culture.—The first sort may be increased by planting cuttings of the young shoots in the summer months, in pots filled with light earth, placing them in the hot-bed under bell- or hand-glasses. When they are become well rooted, they must be carefully removed, and placed in other separate pots, and have the management of other tender plants.

The second sort is raised by planting the small heads from the ends of the branches, in the same manner and at the same season, screening them well from the sun. When perfectly rooted, they should be removed with care into separate pots, and be afterwards well secured against the cold and damp of the winter season, by being placed in a dry green-house, as much air as possible being admitted in mild dry weather.

These are all plants that afford variety and effect among other flowering plants in green-house collections.

GOSSYPIMUM, a genus consisting of herbaceous annual and shrubby perennial plants.

It belongs to the class and order *Monadelphia Polyandria*, and ranks in the natural order of *Columniferae*.

The characters are: that the calyx is a double perianthium: outer one-leaved, trifid, flat, larger: inner one-leaved, bluntly emarginate in five rows, cup-form: the corolla has five petals, obcordate, flat, spreading, fastened by their base to the tube of the stamens: the stamina have numerous filaments, uniting at bottom into a tube, separate at and below the tip, lax, inserted into

the corolla: anthers kidney-form: the pistillum is a roundish germ: style columnar, the length of the stamens: stigmas three or four, thickish: the pericarpium has a roundish capsule, acuminate, three- or four-celled: partitions contrary: the seeds very many, oval, and involved in cotton.

The species cultivated are: 1. *G. herbaceum*, Common Cotton; 2. *G. arboresum*, Tree Cotton; 3. *G. hirsutum*, Hairy American Cotton; 4. *G. Barbadosense*, Barbadoes Cotton Tree.

The first has a tapering woody root, with numerous fibres, annual: the seed-lobes two, kidney-form, terminating gradually in a long petiole with the figure of a halved funnel: the stem three feet high, upright, round, pubescent, as is the whole of the herb, at bottom brown, with slight chinks, at top spotted with black: the branches are axillary, scarcely longer than the leaf at their origin: the leaves are alternate, only half the length of the petiole, tomentose, odorous whilst young. The flowers are of a yellow colour. It is a native of the East Indies, and often known by the title of Levant Cotton.

The second species has the stem eight feet high, the thickness of the human leg, with a rugged brown bark, and long, diffused, twisted branches: the leaves are three- or five-lobed, without glands, smooth, scattered, petioled; the lobes short: flowers entirely yellow, terminating, and solitary. A native of the East Indies, &c.

The third has a shrubby stem, a fathom in height, erect, striated: the branches hirsute: the leaves alternate; the upper ones divided, cordate, acute, entire, rough with hairs about the edge; the lower three-lobed, the lobes little divided, ovate, acute, entire, hirsute beneath, smooth above: the petioles round, striated, dotted with black, hirsute: there is a single glandular pore on the midrib underneath, and sometimes two or three on the next nerves: the peduncles are three times shorter than the petioles, thick, stiff, hirsute, dotted with black. The flowers are yellow, and succeed by large pods.

The fourth species has the stem from six to fifteen feet in height, suffruticose, biennial, and smooth: the branches are almost erect, round, and smooth or pubescent: the leaves alternate, the upper three-lobed, the lower five-lobed; lobes ovate, acute, nerved, smooth above but pubescent underneath: petioles five or six inches long, roundish, patulous, smooth or sometimes pubescent: glandular pores commonly three, on the midribs of the leaves underneath: the peduncles opposite to the petioles and shorter, thickish, round, striated, pubescent, one-flowered: the flowers are large, yellow, turning finally red, succeeded by oval pods. It is a native of the West Indies.

Culture.—All these plants are raised here from seed, which must be sown in pots filled with light earth, in the early spring months, plunging them in the common or bark hot-bed. When the plants have attained a few inches in growth, they should be removed into separate pots, and again placed in the common or bark hot-bed, where they must constantly remain.

The first and third sorts, as being annual, must have the seeds sown every year. The fourth is perennial, and the last biennial.

They flower and produce seeds in the stove, where a few plants afford much variety.

In the West Indies, where these plants are cultivated for the cotton which they produce, the seed, according to Martyn, is set in rows, about five feet asunder, at the end of September or beginning of October, being at first but slightly covered; but when grown and strong, the root is well moulded up. The seed is apt to decay when it is set too deep, especially in wet weather. The soil should not be stiff or shallow, as this plant has a tap-root. The ground must be hoed frequently, and kept very clean about the young plants, until they rise to a moderate height, otherwise they are apt to be destroyed by caterpillars. It grows from four to six feet high, and produces two crops annually; the first in eight months from the time of sowing the seed; the second within four months after the first; and the produce of each plant is reckoned about one pound weight. The branches are pruned or trimmed after the first gathering; and when the growth is over-luxuriant it should be done sooner. When a great part of the pods are expanded, the wool is picked, and afterwards cleared from the seeds by a machine called a gin, composed of two or three smooth wooden rollers of about one inch in diameter, ranged horizontally, close and parallel to each other, in a frame; at each extremity, being toothed or channelled longitudinally, corresponding one with the other; and the central roller, moved with a treadle or foot-lathe, resembling that of a knife-grinder, which makes the other two revolve in contrary directions. The cotton is laid, in small quantities at a time, upon these rollers, whilst they are in motion, and, readily passing between them, drops into a sack, placed underneath to receive it, leaving the seeds which are too large to pass with it behind. The cotton thus discharged from the seeds, is afterwards hand-picked, and cleansed thoroughly from any little particles of the pods or other substances which may be adhering to it. It is then stowed in large bags, where it is well trodden down, that it may lie close and compact; for which purpose some water is occasionally sprinkled upon the outside of the

bag. An acre usually produces about two hundred and seventy pounds on an average. For this use the first and last sorts are mostly cultivated.

GOURD. See **CUCURBITA**.

GRAFT, the shoot or scion which is to be inserted into the stock or branch in the operation of grafting. It is sometimes termed *graft*. Shoots or scions for this use should be cut according to the directions given on grafting, and be always made from such as are not too luxuriant in their growth or infected with disease, such as the canker, &c. See **GRAFTING**.

In this operation, though the vessels of the stock and those of the shoot are joined by the process of inosculation, and those of the latter supplied with nutritious materials from the stock, their economy remains the same. It is considered by Mr. Bradley as a sort of *planting*, the shoot or scion rather taking root in the stock or tree into which it is grafted, than uniting itself with it, as is shown by its preserving its natural purity and use, although fed and supported by a mere crab stock; which it is conceived depends upon some difference in the vessels of the shoot or scion from those of the stock.

GRAFTING, the art of inserting a shoot taken from one tree into the stem or some other part of another, in such a manner as to unite and constitute a perfect plant of the same kind as that from which the branch was taken.

It is by this practice that particular sorts of curious fruit-trees of different kinds are capable of being raised with a certainty of their being the same, or not degenerating. It has been observed, that though the plants raised from seed are liable to run from their kinds, and afford such fruits as are not worth the trouble of cultivation, those procured from shoots taken from such trees as produce good fruit never alter from their kind, whatever the stock or tree on which they are grafted may be; as, notwithstanding the grafts receive their nourishment from the stocks, their varieties are never altered by them, but continue to produce the same kind of fruit as the tree from which they were taken: the only alteration which they undergo is, that when the stocks on which they are grafted do not grow so fast, and afford a sufficient supply of nourishment to the grafts, they do not make so great a progress as they otherwise would do, nor is the fruit they produce so fair, or sometimes so well flavoured.

This process has the advantage, probably from the supply of nutritious matter being not only more abundant but more regular, of rendering the plants or trees which are thus raised more quick in their arriving at the state of maturity or that of bearing.

It is on these different accounts that the practice of grafting is principally had recourse to in raising different sorts of fruit-trees, as well as some particular sorts of ornamental plants of the tree and flower kinds. It also affords the means of growing different kinds of fruits and flowers of the same sort, on the same stock or tree, as several varieties of pears and apples, &c.

There are several different methods of performing this operation, which are distinguished by different terms.

Rind, shoulder, or crown grafting, is that in which the grafts are set in a sort of circle or crown.

It is chiefly practised on large trees, where either the head or the large branches are cut off horizontally, and two or more shoots or scions put in, according to the size of the branch or stem; in performing which the scions are cut flat on one side, with a shoulder to rest upon the crown of the stock; then the rind of the stock is raised up, to admit them between the wood and the bark of the stock, which must be inserted about two inches, so as that the shoulders may meet, and closely join the crown of the stock; and after the whole of the shoots or scions are inserted, all the crown of the stock should be well clayed over, leaving two eyes of the scions uncovered therewith, which will be sufficient for shooting. It is a method of grafting that was much more in practice formerly than at present, owing to the bad success with which it has been attended; for, as the scions are placed between the rind of the stock and the wood, they are frequently blown out by strong winds after they have made large shoots, sometimes after five or six years' growth. Where this method is practised, there should therefore always be some stakes fixed so as to support the scions until they have almost covered the stock or branch. It is usual to perform the operation in this mode about the beginning of April.

Cleft-, stock-, or slit-grafting, which is practised upon stocks, trees, or branches of a smaller size, as from one to two inches in diameter, and may be used with success where the rind of the stock is not too thick, by which the inner bark of the scion will be prevented from joining to that of the stock. In performing it, the head of the stock or branch must be cut off with a slope, and a slit made the contrary way, in the top of the slope, deep enough to receive the scion, which should be cut sloping like a wedge, so as to fit the slit made in the stock; care being taken to leave that side of the wedge which is to be placed outward much thicker than the other: and in putting the scion into the slit

of the stock, great care must be taken to join the rind of the scion exactly to that of the stock; for, if these do not unite, the grafts will not succeed: when this method of grafting is used to stocks that are not strong, it will be proper to make a ligature of bass, to prevent the slit of the stock from opening; after which the whole should be clayed over, to prevent the air from penetrating the slit, so as to destroy the grafts, only leaving two eyes of the scions above the clay for shooting. It is usually performed about the beginning of March.

Whip- or tongue- grafting is the most generally practised by nursery-men, especially for small stocks, or branches of an inch, half an inch, or less, as the scions much sooner cover the stocks in this method than in the others. It is performed by cutting off the head of the stocks sloping; then making a notch in the slope towards the upper part downward, a little more than half an inch deep, to receive the scion, which must be cut with the slope upward, and a slit made in this slope like a tongue, which tongue must be inserted into the slit made in the slope of the stock, and the scion be placed on one side of the stock, so as that the two rinds of both scion and stock may be equal and join together exactly; after which there should be a ligature of bass put round to fasten the scion, so as that it may not be easily displaced, the whole being afterwards clayed over as in the former methods. It may be performed in the early spring months.

Grafting by approach, inarch-grafting, or abtuction, is performed when the stocks that are designed to be grafted, and the tree from which the graft is to be taken, stand so near together as that their branches may be bent and united. It is commonly practised on tender exotic plants, and some other sorts which do not succeed in any of the other methods. In performing the work, a part of the stock or branch is slit off about two inches in length, a smooth part of the stock being always chosen for the purpose; then a small notch made in this slit of the stock downward, in the same manner as directed for whip-grafting; the branch of the tree designed to be inarched having a part slit off in the same manner as the stock, and a slit made upward in it, so as to leave a tongue, which tongue should be inserted into the slit of the stock, joining their rinds equally, that they may unite well together; after which a ligature of bass should be made so as to keep them exactly in their situation, and afterwards this part of the stock clayed over well, to keep out the air. In this method of grafting, the scion is not separated from the tree

until it is firmly united with the stock, nor is the head of the stock or branch, which is grafted, cut off till the same time, and only half the wood pared off with a slope, about three inches in length, and the same of the scion or graft. In this method of grafting, the operation is not performed so early in the season as the others; it being done in the month of April, when the sap is flowing, at which time the scion and stock will join together, and unite much sooner than at any other season or period of the year. It is principally employed in raising jasmynes, oranges, and other exotic trees of the harder kinds.

It has been found that the walnut, fig, and mulberry will take by this method of grafting, while neither of them succeed in any of the other modes. Several sorts of *method* or grafting likewise be propagated by this method or grafting; but all the trees that are grafted in this way are weaker, and never grow to the size of those which are grafted in the other methods; therefore it is rarely practised, except on such sorts of trees as will not take by the other methods of performing the operation.

Root-grafting, which is a late improved mode, is performed by cutting the clean smooth roots of the stocks in pieces five or six inches long, and as large or a little larger than the graft; then they are whip-grafted, and tied together very close, so as to prevent the wet from affecting the wounded parts, planting them so deep as that the graft, which should be four or five inches long, may be about half buried. In this way the grafts themselves will root, and a nearer similitude be preserved to the tree whence the grafts are taken; and after two or three years the stock may be cut quite away, and the graft left to maintain itself. In practising this method the grafts should be an inch or two longer than in the others.

The period or season for grafting should always be regulated by the state of the weather. From the climate being so uncertain in the spring, it is better to defer it till the circulation of the sap is brisk, and the buds of the stocks begin to break into leaves, attention being had that the weak shoots of tender trees will not admit of being so long cut as the more hardy, and that the operation should never be performed while it actually freezes or rains.

Proper grafts.—In providing these, care should be taken that they are shoots of the former year, as when they are older they never succeed well; that they be always taken from healthy fruitful trees, as, when the trees are sickly from whence they are taken, the grafts often partake so much of the distemper as not

to get the better of it, at least for some years; that they be not taken from young luxuriant trees, whose vessels are generally large, continuing to produce luxuriant shoots, and seldom prove fruitful; and that they be taken from the lateral or horizontal shoots rather than the perpendicular ones. They should be cut off from the trees before their buds begin to swell, which is mostly three weeks or a month before the season for grafting; consequently, when they are cut off they should be laid in the ground with the cut part downwards, burying them half their length, and covering their tops with dry litter, to prevent their drying; if a small joint of the former year's wood be cut off with the scion, it will preserve it the better, and when they are grafted this may be cut off; for at the same time the scions must be cut to a proper length before they are inserted in the stocks; but, till then, the shoots should remain of their full length, as they were taken from the tree, which will better preserve them from shrinking; when the scions are to be carried to a considerable distance, it will be proper to put their ends into a lump of clay, and to wrap them up in moss, which will preserve them fresh for a month or longer; but these should be cut off from the trees earlier than those which are to be grafted near the place where the trees are growing. It is, however, always the best practice to cut the grafts as near the time of their being inserted into the stocks as possible.

Stocks proper for grafting upon.—The stocks are the trees or plants for grafting upon; which are either such old trees as are already growing where they are to remain, but the fruit of which is intended to be changed; or such young trees as have been raised in the nursery as a supply to the garden. In the former case, there is no other choice than that of the branches, which should be such as are young, healthy, well situated, and have a smooth bark. Where these trees are growing against walls or espaliers, it will be proper to graft six, eight, or ten branches, according to the size of the trees, by which they will be much sooner furnished with branches again, than when a less number of shoots or scions are put in; but in standard trees, four, or at most six, scions will be sufficient for the purpose.

In choosing young stocks for grafting upon, such as have been raised from the seed, and that have been once or twice transplanted, should always be fixed upon.

After these, those stocks which have been raised from cuttings or layers should constantly be preferred; but those which are suckers from the roots of other trees should be rejected, as

they are never so well rooted as the others, and constantly put out a great number of suckers from the roots, by which the borders and walks of the garden will be always pestered during the summer season. These, besides being unsightly, take off part of the nourishment from the other trees and plants.

And where these stocks have been allowed a proper distance in the nursery where they have grown, the wood will be better ripened and more compact than those which have grown close, and have been there drawn up to a greater height. The wood of these will be soft, and their vessels large; so that the scions grafted into them will shoot very strong; but they will be less disposed to produce fruit than the others; and when trees acquire a bad habit at first it is difficult to reclaim them afterwards. The stocks most adapted to each sort will be explained under their particular genera, and in considering the nature of stocks. See STOCKS.

Implements proper for the work.—These are principally; a neat small *hand-saw*, for cutting off the heads of large stocks; a good strong *knife*, with a thick back, to make clefts in the stocks; with a sharp *penknife*, or *budding-knife*, to cut the grafts with; and a *grafting chisel* and small *mallet*. Other sorts of instruments are sometimes necessary in performing particular sorts of grafting.

Besides these tools, other sorts of materials are wanted in performing the business, such as *bass-strings*, or *woollen-yarn*, to tie the grafts with; and a quantity of good tough clay, which should be prepared a month before it is wanted, and kept turned and mixed, like mortar, every other day, in the following manner:

A quantity of strong good clay, in proportion to the quantity of trees intended to be grafted, should be provided, and some new well-fed horse-dung broken in among it; and if a little cut straw or hay be mixed amongst it, it will hold together the better. The addition of a quantity of salt will also prevent the clay from dividing in dry weather. These should be well stirred together, putting water to them occasionally, in the manner of making mortar. The whole should be hollowed like a dish, filled with water, and kept every other day stirred. It should be carefully kept from being exposed to frost or drying winds; and the oftener it is wrought over the better.

Some have lately made use of another sort of composition for grafting, which has been found to answer the intention of keeping out the air better than the clayey mixture. It is composed of turpentine, bees-wax, and rosin, melted together; which, when of a proper consistence,

is put on the stock round the graft, in the same manner as the clay is usually applied; and, though it be not above a quarter of an inch thick, it keeps out the air more effectually than the clay; and, as cold hardens it, there is no danger of its being hurt by frost, which is very apt to cause the clay to crack, and fall off; and, when the heat of the summer comes on, it melts and falls off without any trouble. In the using it, a tin or copper pot is necessary, with a convenience under it to keep a very gentle fire with small coal; otherwise the cold soon condenses the mixture. It is necessary not to apply it too hot, lest the graft be injured. A person a little accustomed to this composition applies it very fast; and it is much easier for him to work with than clay, especially when the season proves cold.

In the business of grafting, it is found that in long continued dry seasons the grafts are liable to fail in taking, which is sometimes probably owing to the improper choice of the grafts, as well as to the dry weather. Great care should of course always be taken not to graft with weak shoots, particularly those taken from near the top, but such as are taken from the lower end of the shoots, and in which the wood is plump and fresh; as such as are shrivelled seldom or never take well. Where any have missed in the spring, Mr. Forsyth advises to cut off, about the middle or latter end of June, some fine healthy grafts of the sorts that are wished to graft with, and to open the bark in the same manner as for budding, inserting the graft with a piece of the former year's wood on it; and after this has been done, to rub in with a brush some of the composition in a liquid state; then to wrap bass round it, as is done for spring grafting, leaving about three eyes on the shoot, which should be tied on with the bass as tight as possible; then covering the outside of the bass, thus tied up with the composition to the thickness of about one-eighth of an inch, as well as the end of the shoot, to exclude the air and wet. In about three weeks or a month the grafts should be looked over to see if they have taken. When the graft begins to swell, it will throw off the composition; in which case always remember to apply more, to prevent the air from penetrating the incision or wound.

In the month of September, it should be examined whether the wounds are all healed up, and the two barks perfectly united; which, if they are, slacken the bass; and when they are perfectly healed up, it may be wholly taken off; but if not, the bass must be again tied on, and covered with a composition as before, letting it remain till the following spring. It may then

be taken off; and, if it be found that the two barks have separated during the winter, with the point of a sharp knife all the brown part of the bark (which if left would infallibly bring on the canker) should be cut out, and the composition rubbed into the wound. When the grafts have produced strong leading shoots, the tops of them should be pinched off with the finger and thumb; but if they have not shot strong, they should not be cut till the spring, when they may be cut down to three or four eyes, according to their strength, to make them produce horizontal shoots, and form handsome heads. This sort of grafting should always be performed in moist or cloudy weather, if possible.

Mr. Forsyth says that rubbing a little of this composition into the incision will effectually prevent the canker, and in applying it round the graft a much less quantity is sufficient than of the clay; as it need not be more than three inches round in grafting small stems or shoots, and in proportion for those which are larger. It keeps the scion moist. When used in grafting, it should be of such a consistence as to work easily with the hand, or a knife, or small trowel, rather softer than grafting-clay generally is. This method, on a fair trial, will, he thinks, be found "a sure, neat, and expeditious way of grafting."

In grafting or budding, it should be performed as near to the upper side of a bud as possible, and "the most proper place for inserting the scion or bud is at the joint a little above the cross shoot."

In respect to the sorts of trees that will succeed upon one another, it may be observed, that all such as are of the same genus, that is, which agree in their flower and fruit, take upon each other; hence all the nut-bearing trees may be safely grafted on each other, as well as all the plum-bearing trees, as the several sorts of plums, almond, peach, nectarine, apricot, &c. but as many of them are subject to emit gum from the parts wounded, as the peach and nectarine kinds, it is found the surest method to bud or inoculate them.

All such trees as bear cones also do well upon each other, though they may differ in one being evergreen, and the other shedding its leaves in winter; as in the cedar of Libanus and the larch-tree, which are found to succeed upon each other; but they must be grafted by approach, as they abound with a great quantity of resin, which is apt to evaporate from the graft when separated from the tree before it is joined with the stock; whereby they are often destroyed. The laurel likewise on the cherry, or the cherry

on the Laurel. All the mast-bearing trees are also found to take upon each other, and those which have a tender soft wood do well if grafted in the common way; but such as are of a firm contexture, and are slow growers, must be grafted by approach.

It is likewise by this method that many kinds of exotic trees are not only propagated, but also rendered hardy enough to endure the cold of our climate in the open air; as by being grafted upon stocks of the same sort which are hardy, the grafts are rendered more capable of enduring the cold.

GRAINS OF PARADISE. See **AMOMUM**.

GRASS-GROUND, the parts of ornamented grounds which are kept in the state of short Grass or sward. Those spaces which are extended in the fronts of the houses or habitations, and are termed lawns, are mostly kept in short grass, which by their constant verdure, summer and winter, and open rural appearance, exhibit a fine imitation of nature at all seasons, especially when the side-boundaries terminate in rural plantations in various natural curves and bendings. This mode of laying out pleasure-grounds prevails much at present. But besides these, it is the practice to have rural short Grass openings continued between the plantations throughout the different districts of grounds of this sort, separating and bounding the shrubby clumps, borders, and other parts, in some places widely spreading, in others more contracted; but, in either case, extending to the boundaries of the several plantation compartments, in various bendings, sweeps, and curves; by which the whole is rendered rurally ornamental, and at the same time more agreeable and easy to walk on than gravel between the plantations when the weather is dry and hot during the summer season. In the antient style of gardening, it was much the custom to have straight short Grass-walks, both for ornament and common walking upon: but for ornament, unless elegantly wide and spacious, they have a littleness in their general appearance, as may be seen where long narrow slips of short Grass-Ground are extended to some distance, in the way of walks; and for the latter purpose they are very improper in winter and all moist weather; and even in summer in the mornings and evenings, as being always damp and dewy. Walks of this kind should therefore be but sparingly introduced; and where any are made for variety, ornament, or summer's walking, they should be as spacious as the situation admits, not less than from ten to fifteen feet wide, and even twenty feet wide or more, when the walk is considerably extended in length.

The method of forming short Grass-Ground

work, is either by sowing the parts with Grass seeds, or by laying them with turf, cut from a fine field, common or down; the latter of which, where it can be obtained at a moderate expense, is greatly preferable, as it not only at once forms a complete sward, but is generally more close, even, and smooth, as well as less apt to run up to benty Grass, grow rank, or rise in tufts, than by the sowing method.

In preparing the ground either for sowing Grass seeds upon or laying with turf, the whole must be broken up equally to a moderate spade deep, clearing out all roots of perennial weeds and other coarse materials. When this has been done, stakes or wooden pegs, with notches, for marking the level, according to the position of the ground, must be driven in; then proceed with line and spade to rough-level the ground according to the marks or levels on the pegs, afterwards treading, rolling, or ramming the whole down equally, that it may nowhere sink in hollows afterwards. When this has been finished, the levels should be wrought off more accurately, and the whole finished with a neat raking, clearing off all large stones, and making an even and smooth surface; in this state, it may either be sown with grass seed, or laid with turf.

For the first method, the proper seasons for sowing are either February, March, and April, or in August or September, in moist weather. In moist wet soils the former is probably the best, but in those of a dry gravelly nature, the latter. In this business it is of the utmost consequence to procure good seeds; those from hay-stacks or out of hay-lofts are often used, which may answer well, where the hay was the growth of some fine pasture free from weeds, and naturally afforded fine turf when grazed and mowed; but in other cases, there is often a mixture of various sorts with weeds, by which the sward is rendered irregular and foul, and never makes handsome short Grass-Ground. If you are not furnished with seeds of your own, they may be obtained from the seedsmen, and should be of those kinds which strike deep root, spread out laterally in their tops, are permanent, and capable of resisting the effects of heat; there are many of this kind. The seed must be sown broad-cast, very thick and regular over the surface, and directly raked or harrowed in; and when the surface is dry, it should be rolled with a wooden roller, to bury the seeds more effectually and make a smooth surface; when the grass comes up, all weeds should be removed; and, the same season, when the sward is become thick and green, and advanced some inches in growth, it should be mowed, rolling it well afterwards, and continue mowing it and rolling

two or three times the first summer, especially if it were sown in spring; as the oftener it is mowed and rolled, the thicker and finer it will grow; and, if it be intended to keep the Grass tolerably fine, mowing will be requisite once a week or fortnight, according to the growth, from April till October, and rolling once a week or fortnight, in moderately dry weather; and occasionally in the winter season. In this way a good turf may be formed in a few years.

In the second method, which should always be employed where it can with convenience, the best turf is that of a fine pastured common or down, where the sward is fine and short.

The best season for laying the turf is from September till March or April, though it will grow at almost any time of the year, even, if there be occasion, in summer.

Turf for this use is mostly cut or flayed with an iron instrument called a turving-iron; all the turfs being cut of an equal width, length, and thickness; the proper size is a foot wide, a yard long, and about an inch in thickness. They should be first marked by a line, the proper width, length, and depth, and then cut with a racer or cutter, first longways a foot wide, then across in yard lengths, proceeding afterwards to cut them up; having particular regard to cut them level, all an equal thickness, otherwise it will be impossible to lay them level. As they are cut, they should be rolled each up close and tight, the grass side inwards, and piled up by tens, especially if they are cut by the hundred, which is mostly the case. This is usually done at from about a shilling to fifteen-pence the hundred, according to the nature of the soil, as whether soft and easy to cut, or hard and stony. A man will cut from three to five, six, or seven hundred a day, or more, if very soft easy-cutting turf, with a person to race them out, and roll them up, as they are cut.

The method of laying them is very easy: they are placed regularly turf and turf, unrolling them as they are laid, joining them up quite close edge to edge, and making good all deficiency of broken parts as the work proceeds; and as soon as laid, they should be well beaten with broad heavy wooden beaters, as flat pieces of elm or oak plank, two inches thick, fifteen or eighteen inches long, and a foot broad, having long handles fixed slanting in the middles of the upper side. With these beat the grass regularly all over, and then roll it well with a heavy iron or stone roller, repeating these operations in moist weather.

When very dry hot weather succeeds, so as to occasion the turf to shrink and open at the joints, a good watering is of much advantage.

The management of short Grass-ground after it has been thus laid down, is that of mowing it in summer frequently, to keep it short and fine, like a pastured down; poling occasionally with a long pole, to scatter the worm-casts, which greatly deface all short grass, and rolling it frequently both to take up the scattered worm-casts to make the surface clean, and to render it smooth, firm, and even.

Mowing once a week, ten days, or fortnight, or according to its general growth, during the summer, is necessary, especially for the principal home lawns, and other short Grass-grounds in the most conspicuous parts, which parts should always be kept very close and fine, like the sward of a fine pastured down or common: it is performed with a short grass-scythe; and dewy mornings, or moist weather, must always be chosen for the work, as it will be impossible to mow short Grass properly in dry weather. Previous to mowing, it is of advantage sometimes to pole and roll the grass the day before it is intended to mow: in performing the work of mowing, proper attention is necessary not to score, or leave the marks of the strokes of the scythe, which has a very unsightly appearance; to prevent which as much as possible, the point of the scythe should be laid out rather wide, an inch or two beyond the measure of heel and point, especially for very short grass; keeping the point rather out, and not drawing that part too fast inward, gathering the grass neatly to the left in a range, and after having mowed thus to the end of the swarth, to mow it lightly back again, in order to trim off all scores and other irregularities, unavoidably left the first time in executing the work.

After it has been all thus mown over, proceed to sweep up the mowings of each swarth regularly, by standing in the middle, sweeping it along alternately to the right and left to the end of the swarth, forming all the grass in a range on each side; then sweep up the ranges in large heaps, and carry the whole off directly in a wheel-barrow, large basket, or other contrivance.

The business of poling is performed by a long taper pliable ashen pole, fifteen or eighteen feet long, by passing it backwards and forwards in rather dry weather, so as to break and scatter the worm-casts about. The grass should be afterwards rolled with a wooden roller when the surface is a little moist, but not too wet, by which the earth will all adhere to the roller, and render the surface perfectly clean; the work being repeated, as there may be occasion, the year round; and in mowing-time, if the surface is foul, it is particularly necessary to pole and roll on the day previous to mowing, by which a clean

smooth surface will be provided, so as to be able to mow close, even, and more expeditiously.

In the rolling of short Grass-grounds, it should be performed occasionally with a wooden roller, and a heavy iron or stone roller: the wooden roller is proper after mowing, to clean up the worm-casts and smooth the surface, being performed when the surface is not very wet, especially if full of worm-casts, as it would otherwise plaster and daub the grass, and render it unsightly; the heavy iron or stone roller should be used occasionally, when the surface is dry, to press down all inequalities close, so as to preserve a firm, even, smooth surface. And in fine-kept short Grass-grounds, the rolling should be performed occasionally a day or two before mowing, to settle the surface firm and smooth, which greatly contributes to the easy and exact performance of the work: the business of rolling in small or but moderately large short Grass-grounds is mostly performed by men; but in very extensive grounds, it is sometimes done by a horse; having a large roller for the purpose, with shafts like a cart, and the horse at the time wearing a sort of leather shoes, very broad at bottom, made so as to lace on occasionally like men's half-boots, to prevent his feet cutting the surface in holes, and rendering it uneven.

Where short Grass-grounds are defaced by wild daisies, dandelion, or other weeds, the first may be removed by having the blade of an old broadsword fixed in the end of a long pliable pole, which, as it cuts both ways, by sweeping it backwards and forwards it will head down the daisies at a great pace; which may be repeated two or three times a week, or as often as there may be occasion.

The others should be extirpated by means of an iron for the purpose, made in the form of a small docking-iron.

In the autumn-finishing mowings, the grass should be generally cut down as close and even as possible, that the sward may remain in a neat even surface over the winter season.

These directions for the management of short ornamental Grass-grounds regard only such as are required to be kept constantly short, close, and even in the surface, as is necessary in the principal lawns, plats, walks, and other divisions, situated within the limits of the main pleasure-ground. In the outward considerably extended districts continued into fields, parks, &c. it is not necessary to have them cut so frequently; two or three common mowings in a summer, with occasional rollings afterwards, may be sufficient.

GRAVEL, a small stony substance made use of for the purpose of constructing roads, walks, and paths. Walks formed of this material are great ornaments to gardens and pleasure-

grounds, as well as useful for common walking upon.

The best Gravel for these purposes, is that which is naturally composed of irregular pebbles and flints, having a moderate proportion of a yellowish or brownish sandy loam, to make it bind, and give colour: it is obtained in fields and commons in many parts, at from one to three or four feet under the surface, though not equally good in all parts in respect to quality and colour; some having a greater or lesser proportion of pebbles, a larger or smaller proportion of loam, which is more or less sandy or clayey: it is the colour of the loam principally which constitutes the beauty of Gravel-walks; that of a deepish yellow or reddish colour being the most eligible, as when formed into well-laid walks and rolled, it has an exceedingly beautiful and ornamental effect. Where such Gravel can be procured within a moderate distance, and easy expense, it is preferable to all others; in some parts, Gravel is of an iron-mould colour, or of a dusky-brown hue; which may nevertheless be of a proper quality for walks, where the colour is disregarded.

Whatever colour the Gravel may have, its proper quality for walks is, a due proportion of moderate, light, sandy loam, to make it bind close and firm at all seasons; but not so redundant, or so clayey, as to be clammy and stick to the feet in wet weather, or so sharp and sandy as to become open and loose in dry weather.

In some places, no other Gravel is met with but such as is very loose, sandy, or pebbly, and which has scarcely any binding materials amongst it; which kind never of itself binds, but always remains open and loose, being at all times disagreeable to walk on: this, therefore, must be mended by a mixture of light sandy loam, where practicable, adding about one load to every two or three of Gravel, casting them together, and turning them over two or three times, that they may be well blended and incorporated; and this, when formed into a walk, will often bind close, firm, and smooth at all seasons.

In preparing the Gravel for walks, it should not by any means be finely screened, as is often the practice: as it is dug out of the pit, it is only necessary to cast it up in a heap, or long ridge, all such large rough pebbles only as roll down being cleared away; as if screened from the stones, it partakes too much of the loam, so as always to stick to the feet at every flash of rain.

In purchasing Gravel for walks, it is mostly from about two to five or six shillings or more per cartload for three horses; though the price differs greatly in different parts, and according to the nature of the Gravel.

In respect to the distribution of Gravel walks in pleasure-grounds and gardens, for ornament or use, large ones are necessary to proceed immediately parallel to the house, extending each way towards the side districts of the garden and ornamented grounds; according to the former style of gardening, a large walk of this kind was usually extended in a straight line from the front of the habitation along the middle of the pleasure-ground, sometimes having grass plats continued on each side, and sometimes spacious borders furnished with curious shrubs and flowers. But in modern designs these middle walks are rarely admitted, especially in spacious grounds, having nothing in front beyond the parallel habitation-walk, but an open rural grass lawn, free from all intersections of walks, &c. However, a good walk closely parallel to the house is indispensably necessary, both for ornament and convenience; and from this, side-walks should branch off, communicating with the other parts of the pleasure- or garden-grounds; one in particular to be extended in a serpentine manner quite round the ground, others leading in the same manner through the interior parts, so as to have dry firm walking at all times to every part of the ground or garden without coming upon the grass.

The dimensions for Gravel-walks, must be regulated according to the extent of the grounds or gardens, as from five to twenty feet or more in width; but all principal walks should be at least eight or ten feet wide; and in large grounds or gardens, leading directly from the house, they should be ten, fifteen, or twenty feet wide at least. Where the houses and gardens are very large, the main walks contiguous to the mansion are sometimes made thirty or forty feet wide; the boundaries on each side being sometimes in grass widely extended, and sometimes in borders for flowers and other curious plants, having either narrow verges of grass, or edgings of dwarf-box, or thrift, on the sides of the walks.

In forming walks of this sort, they should be first staked out to the proper width, and then the boundaries formed, each side of equal level, corresponding to the adjacent ground; the cavity of the walk for the reception of the Gravel being afterwards made, the whole space being dug out ten or twelve inches deep, to allow for a proper depth of Gravel, both to prevent weeds rising from the ground below, and worms from casting up the earth; as also to allow of a proper depth for turning the Gravel occasionally when the surface becomes foul: the earth dug out to form the cavity of the walk, may be used to raise and form the ground on each side, if necessary, which, and the edgings, should always

be completed before the Gravel is begun to be laid.

When the cavity has been thus prepared, any hard rubbishy materials may be laid in the bottom, several inches thick; such as coarse Gravel or ballast, rough stony lime, brick, or other rubbish, which will greatly prevent worm-casts, and help to drain the moisture from the top of the walk in wet weather, and in winter preserve a dry surface: the proper Gravel is then to be laid six or eight inches thick; in laying, raising the middle higher than the sides, in a gradual rounding form; which is not only necessary to throw off the wet, but also to give the walk a more ornamental appearance; the proportion to be observed in this is, for a walk of five or six feet width, an inch and a half of rise in the middle; for one of ten or twelve feet, two and a half inches; and for one of twenty feet, from three to four or five inches; the same proportion being regarded in other widths. At every ten or fifteen feet, as the work advances in laying, it is proper to tread, rake, and roll the Gravel down, as it always rolls more firm and smooth whilst fresh stirred; it is also necessary, for fear of rain, especially in loamy Gravel; for which reasons more should never be laid in one day than can be finished off, except the rough laying. The treading should be performed regularly with the feet pretty close, taking short steps; so as to render every part equally firm, and not to sink in holes under the feet, in the work of raking and rolling. The raking should be performed regularly lengthways of the walk; and in the finishing off or smooth-raking, a wooden-headed rake without teeth is most eligible, or the back of any common rake; as by either of these the surface may be rendered more regular and even without drawing off the requisite proportion of top pebbles, or raking them into holes or heaps; as the art of smooth-raking is to leave all the proper-sized top stones equally dispersed over the surface. As soon as any part is thus laid and raked, it should be well rolled, both across and lengthways; and when the whole is laid, a good rolling should be given the whole length, repeating it till the surface is rendered perfectly compact, firm, and smooth; and after the first shower of rain, another good rolling should be given, so as to make it bind like a rock. This method should be practised in all walks made with this material.

The management afterwards is, occasional weeding, sweeping, and good rolling once or twice a week, especially in the advanced part of spring, and all summer; and also occasionally in winter, in dry open weather; and when the surfaces become very foul, or overrun with

small weeds or moss, as is often the case, they must be broken up in spring, and turned, the surface to the bottom, and the bottom to the top, by which the weeds and moss will not only be buried, but the walks appear as fresh as when new laid. The custom of breaking up Gravel-walks in the beginning of winter, and laying them up in rough ridges, to destroy weeds and moss, is not eligible for general practice, or only occasionally, where any walk is exceedingly over-run; it is mostly more advisable to permit all the principal Gravel-walks to remain undisturbed, at least till the spring, when, if it appear necessary, the whole may be broken up, regularly turned, and re-laid in a neat manner.

The turning of Gravel is a sort of slight digging, the foul surface being turned down and the fresh up; some have it performed regularly once a year in the early spring, in order to preserve the colour. In these cases, the laying, raking, and rolling are performed the same as in the first constructing the walks.

The rolling should be performed once a week at least, in summer, but if two or three times, the more beautiful the walks will appear, and it will tend greatly to destroy weeds and moss: it is mostly a rule among gardeners, to sweep and roll every Saturday. During the summer it is of much advantage to give a good rolling after rain, which preserves a compact smooth surface.

GREEN-HOUSE, a sort of building fronted and covered with glazed frames, destined for the purpose of preserving various sorts of exotic plants through the winter season: the aid of artificial heat is not here necessary, except in very intense cold weather. It is advisable, in constructing such houses, to erect flues to use occasionally, which may prove serviceable, not only in severe frosts, but also in moist foggy weather, when a moderate fire now and then will dry up the damps, which would otherwise prove pernicious to many of the tender kinds of plants.

It differs from the conservatory chiefly in this circumstance, that the plants, trees, or shrubs are in pots or tubs, and placed upon stands, frames, or stages, during the winter, to be removed to proper situations in the open air in the hot summer season; while in that there are beds, borders, and clumps laid out in the ground plan, and made up with the best earthy materials to the depth of three or four feet, in which the shrubs, trees, &c. are regularly planted; the whole of the roof being removed during the summer to admit fresh air, and replaced on the approach of the autumn, to remain till the following summer.

Green-Houses are at present mostly contrived to stand in the pleasure-ground, near to the house if possible. They should be upon a somewhat elevated and dry spot, full to the south, and where the sun has access from its rising to its setting: the buildings are commonly of brick or stone, having the fronts and tops almost wholly of glass-work; and ranging lengthways east and west. They are generally constructed upon some ornamental plan. As to the general dimensions in respect to length, width, and height, they may be from ten to fifty feet or more in length, according to the number of plants to be contained; and in width, from ten or fifteen to twenty feet; but for middling houses, fifteen or eighteen feet is a sufficient width; and in height in the clear, nearly in proportion to the width.

The walls on the backs and ends, particularly the former, should be carried up two bricks thick; and if more than fifteen feet high, two bricks and a half thick; at one end of the back wall, on the outside, it is eligible to erect a furnace, for burning fires occasionally, communicating with flues within, ranging in two or three returns along the back wall, having one flue running along the front and end walls, raised wholly above the floor.

The fronts of the buildings should have as much glass as possible, and wide glass doors should be made in the middles, both for ornament and entrance, and for moving in and out the plants. It would also be convenient to have a smaller entrance door at one end: the width of the windows for the glass sashes may be five or six feet; and the piers between the sashes may be either of timber, six, eight, or ten inches wide, according to their height, or, if of brick or stone-work, two feet wide at least, sloping both sides of each pier inward, that by taking off the angles, a freer admission may be given to the rays of the sun: for the same reason the bottoms of the sashes should reach within a foot of the floor of the house, and their tops almost as high as the roof; and if brick or stone piers two feet wide, shutters may be hung on the inside to fall back against each pier: the roof may be either wholly or half glass-work, next the front; the other half slated, especially if the upright or front piers are of timber; and shutters to cover the top glasses may be contrived so as to slide under the slated roof: where the piers are of brick or stone, it is common to have the roof entirely slated or tiled; but slating is the most ornamental, either for a half or whole roof; and the ceiling within should be lathed, which, as well as the whole inside wall, must be well plastered and white-washed.

In Green-Houses of modern construction, in order to have as much glass as possible in front, the piers between the sashes are commonly of timber only, from six to eight or ten inches thick, according to the height, so as to admit as great a portion of light and heat of the sun as possible, and the roofs wholly of glazed frame-work.

Green-Houses for large collections of plants have sometimes two wings, of smaller dimensions, added to the main building, one at each end, in a right line, separated sometimes from it by a glass partition, with sliding sashes for communication, and the front almost wholly glass-work, and half or whole glass roofs. Thus by these additional wings, the houses consist of three divisions, whereby the different qualities and temperatures of the various plants can be more eligibly suited. The middle or main division may be for all the principal and more hardy, woody, or shrubby kinds, which require protection only from frost; one of the wings appropriated to the succulent tribe; and the other to the more tender kinds that require occasional heat in winter, but which can live without the heat of a stove.

On whatever plans Green-Houses are constructed, the whole of the inside walls should be neatly finished off with plaster and white-wash, and the wood-work painted white; the bottom being paved with large square paving tiles, or some other similar material.

In the Green-House there should be stands, frames, or tressels, which may be moved in and out, upon which rows of planks may be fixed, so as to place the pots or tubs of plants in regular rows one above another; by which their heads may be so situated, as not to interfere with each other. The lowest row of plants next the windows being placed about four feet from them, that there may be a convenient breadth left to walk in front; and the rows of plants should rise gradually from the first, in such a manner that the heads of the second row be entirely advanced above the first, the stems only being hid; and at the back of the house a space allowed of at least five feet, for the convenience of watering the plants, and to admit a current of air round them, that the damps occasioned by their perspiration may be the better dissipated; which by being pent in too closely often occasion a mouldiness upon the tender shoots and leaves, and when the house is close shut up, this stagnating rancid vapour is often very destructive; for which reason they should never be crowded too close to each other, nor should succulent plants ever be placed among them.

In the annexed plate is the plan and elevation of an improved Green-House, in which fig. 1. is the front elevation, fig. 2. the ground plan, fig. 3. a section.

GREEN-HOUSE PLANTS, such as require the protection of this sort of building during the winter or other season: the following are the principal of the different sorts that require this sort of management.

SUCCULENT KIND.

Agave, *Agave* or *American Aloe*, comprising Common great American Agave, with entire green leaves, and a branching flower-stalk.—Common Agave, with striped leaves.—Virginia Agave, with narrower pale-green leaves.

Aloe, *African Aloe*, containing Mitre-shaped Aloe—Tree, or Sword Aloe—Aloe Ferox—Fan Aloe—Succotorine Aloe—Soap Aloe—Partridge-breast Aloe—Tongue Aloe—Warted-Tongue Aloe—Pearl-Tongue Aloe—Cobweb Aloe—Hedge-hog Aloe—Cushion Aloe—Spiral Aloe—Pentangular Spiral Aloe—Triangular Spiral Aloe—*Iris Uvaria* Aloe.

Anthericum, *Spider-wort*, containing Shrubby-stalked, Onion-leaved Anthericum—Aloe-leaved Anthericum—Mock Asphodel Anthericum.

Cacalia, *Foreign Colts-Foot*, comprising Cacalia Ficoides—Kleinia, or Indian Cacalia—Anteuphorbium Cacalia—Papillary Cacalia.

Cactus, *Melon Thistle*, containing Cactus Opuntia, or Common Indian Fig.

Cotyledon, *Navel-wort*, containing Round-leaved—Long-leaved—Hemispherical-leaved.

Crassula, *Lesser Orpine*, containing several species.

Euphorbia, *Euphorbium*, containing most of the sorts.

Mesembryanthemum, *Fig Marigold*, containing many curious species.

Sempervivum, *Live Ever*, or *House-Leek*, containing Tree House-Leek—Variegated Tree House-Leek—Lesser Canary-Tree House-Leek.

HERBACEOUS KIND.

Antholyza, *Ethiopian Corn-Flag*, containing Ringent Scarlet Antholyza—Ethiopian Crimson Antholyza—Cunonia, or Large Spathed Scarlet-Flowered.

Antirrhinum, *Snap-Dragon*, containing Variegated Snap-Dragon—Gibraltar Spotted-Flowered Linaria—Dalmatian Toad-Flax.

Aristolochia, *Birth-wort*, containing Evergreen Aristolochia—Pistolochia, or Small Birth-wort.

Bryonia, *Bryony*, containing African Tuberous-rooted Bryony.

Calla, *Calla*, containing Sweet Calla, or Ethiopian Arum.

Campanula, *Bell-flower*, containing American Bell-flower.

Canarina, *Canarina*, containing Canary Bell-flower.

Canna, *Indian flowering Reed*, containing Common Indian flowering Reed, and varieties—Glaucous Indian Reed.

Crinum, *Asphodel Lily*, containing African Asphodel Lily—Broad-leaved Asphodel Lily.

Cyclamen, *Cyclamen*, containing Persian Cyclamen, and several varieties.

Erodium, *Erodium*, containing Pentandrous Geranium, or Crane's-Bill—Thick-leaved Erodium—Upright—Dwarf Erodium.

Erythrina, *Coral-Tree*, containing Herbaceous Erythrina.

Ixia, *Ixia*, containing African Woolly-headed Ixia—Bulbiferous Ixia—Flexuous Ixia—Corymbose spotted-flowered Ixia.

Leonurus, *Lion's Tail*, containing African Scarlet Leonurus—Striped-leaved Leonurus.

Ornithogalum, *Star of Bethlehem*, containing Cape Ornithogalum.

Tropæolum, *Indian Cress*, containing Double Indian Cress, or Nasturtium.

SHRUBBY KIND.

Andromeda, *Andromeda*, containing Tree Andromeda, or Carolina Sorrel.

Anthospermum, *Amber-tree*, containing Ethiopian Smooth Amber-tree—Ciliated Amber-tree.

Anthyllis, *Jupiter's Beard*, or *Barba Jovis*—Common Barba Jovis, or Silver Bush—Spanish ternate-leaved Barba Jovis—Dwarf Portugal Barba Jovis—Erinacea, or Prickly Anthyllis.

Arctotis, *Arctotis*, containing Rough-leaved Arctotis—Narrow-leaved Arctotis—Sea Ragwort-leaved Arctotis—Plantain-leaved Arctotis.

Artemisia, *Mug-wort*, containing Tree-Wormwood.

Asclepias, *Swallow-wort*, containing Shrub Asclepias.

Asparagus, comprising White Prickly Asparagus—Declinated Bristly-leaved Asparagus—Acute-leaved Asparagus—Retrofracted Great Prickly Asparagus.

Aster, *Star-wort*, containing Shrubby African Aster.

Astragalus, *Milk-vetch*, &c. comprising the Tragacanth, or Goat's-thorn, and several varieties.

Atropa, *Deadly Night-shade*, containing Shrubby Deadly Night-shade of Spain.

Baccharis, *Plumghman's Spikenard*, containing Ivy leaved Baccharis—Oleander-leaved Baccharis—Halimus-leaved Baccharis.

Bosea, *Yerva-moru*, or Shrubby Golden-red Tree.

Brunia, containing Knot-flowered, or Imbricated-leaved—Woolly, heath-leaved—Abrotanoides, or Thyme-leaved—Radiated Brunia.

Bubon, *Macedonian Parsley*, containing Shrubby Galbaniferous Bubon—Shrubby Gum-miferous Bubon.

Buddleia, comprising American long-spiked—Occidental American—Globular-headed Buddleia.

Bupthalmum, *Ox-eye*, containing Shrubby Jamaica Ox-eye—Maritime, or Sea Ox-eye.

Bupleurum, *Hare's-ear*, containing Shrubby Ethiopian Hare's-ear—Shrubby Difforme-leaved Cape Hare's-ear.

Calendula, *Marigold*, containing Shrubby Cape Marigold—Shrubby Grass-leaved Ethiopian Marigold.

Capparis, *Caper Bush*, containing Spinous Capparis, or True Caper Shrub.

Cassine, *Cassine*, containing Cape Phillyrea—Maurocenia, or Hottentot Cherry.

Ceanothus, *Ceanothus*, containing African Ceanothus.

Celastrus, *Staff-tree*, containing Pyracantha-leaved Celastrus—Box-leaved—Myrtle-leaved Celastrus.

Ceratonia, *Carob-tree*, comprising Common Carob-tree, or St. John's Bread.

Chamærops, *Chamærops*, containing Dwarf Palm.

Chrysanthemum, containing Shrubby Canary Chrysanthemum—Shrubby Floscular Chrysanthemum.

Chrysocoma, *Goldy-locks*, containing Shrubby Coma Aurea, or Greater African Goldy-locks—Shrubby Nodding Goldy-locks.

Cistus, containing Bay-leaved Cistus—Sea-Purslane-leaved Cistus; and several other species.

Citrus, *Citron-tree*, containing Lemon-tree, and Orange, with all the varieties of each.

Cliffortia, *Cliffortia*, containing Ilex-leaved Cliffortia.

Cluytia, *Alaternoides Cluytia*, containing Purslane-leaved Cluytia—Elateria, or Indian Cluytia.

Colutea, *Colutea*, containing Shrubby Ethiopian Scarlet Colutea.

Convolvulus, *Convolvulus*, comprising Evergreen Canary Convolvulus—Silvery Convolvulus.

Coronilla, containing Valentine Coronilla—Glaucous Coronilla—Silvery Coronilla.

Dais, *Dais*, containing Cotinus-leaved Dais.

Digitalis, *Fox-glove*, containing Shrubby Canary Fox-glove.

Diosma, *African Spiræa*, containing Opposite-leaved—Hairy-leaved—Red Diosma, &c.

Ehenu, *Ebony*, containing Ebony of Crete.
Genista, *Broom*, containing Shrubby Canary Broom.

Geranium, *Geranium*, containing all the shrubby kinds.

Gordonia, *Gordonia*, containing Loblolly Bay.

Gorteria, *Gorteria*, containing Shrubby prickly-leaved *Gorteria*.

Grewia, *Grewia*, containing Occidental *Grewia*.

Halleria, *Halleria*, containing African-fly Honeysuckle.

Heliotropium, *Turn-sole*, containing Shrubby Peruvian *Heliotropium*.

Hermannia, *Hermannia*, containing *Althæa*-leaved—Alder-leaved—Lavender-leaved—Gooseberry-leaved *Hermannia*.

Hypericum, *St. John's Wort*, containing Warty-leaved Minorca *St. John's Wort*—Carolina *St. John's Wort*—China Monogynous *St. John's Wort*.

Jasminum, *Jasmine*, containing Catalonian *Jasmine*—Azorian *Jasmine*—Yellow Indian *Jasmine*.

Iberis, *Candy-tuft*,—Evergreen Tree Candy-tuft, Evergreen Striped-leaved Candy-tuft—Everflowering Tree Candy-tuft.

Justicia, *Malabar Nut-tree*.

Lantana, *American Viburnum*, containing African *Lantana*, or *Ilex*-leaved *Jasmine*—Sage-leaved *Lantana*.

Laurus, *Bay-tree*, containing Carolina Blue-berried Bay—Red-berried Bay-tree—Indian Bay-tree—Cinnamon-tree—Camphire-tree—Deciduous Bay-tree.

Lobelia, *Lobelia*, containing Shrubby, Pine-leaved, Blue *Lobelia*.

Lycium, *Box-thorn*, containing African Box-thorn—Barbary Box-thorn.

Malva, *Mallow*, containing African Shrub Mallow.

Medicago, *Medicago*, containing Shrubby Hoary *Medicago*, or Moon Trefoil.

Melia, *Melia*, containing Bead-tree.

Mentha, *Mint*, containing Tree-Mint.

Morea, *Morea*, containing Canaliculated-leaved *Morea*—Rush-leaved *Morea*.

Myrica, *Gale*, *Sweet Willow*, and *Candleberry Myrtle*, containing Oak-leaved *Myrica*—*Æthiopian Heart-leaved Myrica*.

Myrtus, *Myrtle-tree*, containing Common *Myrtle*, which comprehends many varieties.

Nerium, *Oleander*, or *Rose-bay*, comprising Common *Oleander*, with red flowers, scarlet flowers, white flowers, double flowers, striped leaved.

Olea, *Olive-tree*, containing European *Olive-tree*—Cape, or African *Olive-tree*.

Ononis, *Rest Harrow*, Shrubby Spanish *Ononis*.

Osteospermum, *Osteospermum*, containing hard-seeded *Chrysanthemum*.

Othonna, *Ragwort*, containing Pectinated-leaved *Othonna*—Southernwood-leaved *Othonna*.

Passerina, *Sparrow-wort*,—Shrubby African *Passerina*.

Pelargonium, *African Geranium*, containing many shrubby species.

Phlomis, *Jerusalem Sage*, containing Yellow *Phlomis*, and varieties—Purple *Phlomis*.

Physalis, *Physalis*, containing *Alkekengi*, or Winter Cherry—Somniferous Winter Cherry—Flexuous Winter Cherry.

Pistacia, *Pistachia Nut*, and *Mastic-tree*, two or three varieties.

Polygala, *Milk-wort*, containing Shrubby Myrtle-leaved *Polygala*.

Portulaca, *Purslane*, containing Shrubby Cape Purslane-tree.

Poterium, *Burnet*, containing Shrubby Prickly Burnet.

Prasium, *Shrubby Hedge Nettle*.

Protea, *Silver-tree*, containing Common Silvery *Protea*, or Changing-tree—Coniferous *Protea*.

Punica, *Pomegranate-tree*, containing Dwarf Pomegranate.

Rhus, *Sumach*, containing African Hoary Sumach, and varieties—African Narrow-leaved Sumach, and varieties—Shining-leaved African Sumach.

Royena, *Royena*, containing African Bladder-nut.

Rumex, *Dock*, containing Sorrel-tree.

Ruscus, *Knee-holly*, containing Alexandrian Laurel—Tongue-upon-tongue Laurel.

Salvia, *Sage*, containing Shrubby African Golden-flowered Sage—Shrubby African Blue-flowered Sage—Canary Sage—Mexican Sage, or Shrubby Mexican Clary.

Scabiosa, *Scabious*, containing Shrubby Scabious.

Senecio, *Groundsel*, containing Shrubby African Groundsel.

Sideritis, *Iron-wort*, containing Canary Iron-wort—Cretan Iron-wort.

Solanum, *Night-shade*, containing *Amomum Plinii*, Bastard Capsicum, or Winter Cherry—African Jagged-leaved *Solanum*, or *Pomum Amoris*—American Twin-fruited *Solanum*—Thorny, Downy Night-shade.

Tanacetum, *Tansey*, containing Shrubby

Æthiopian Tansey—Under-shrubby *Samphire-leaved Tansey*—Tree *Tansey*.

Tarchonanthus, *Tarchonanthus*, containing *Shrubby African Fleabane*.

Tetragonia, *Tetragonia*, containing *Shrubby Tetragonia*.

Teucrium, *Germander*, comprising *Spanish Tree-Germander*—*Broad-leaved Tree-Germander*.

Vitex, *Chaste-tree*, containing *Evergreen Chaste-tree*.

Ulex, *Furze*, or *Whins*, containing *African Berry-bearing Furze*.

Xeranthemum, *Xeranthemum*, containing *Broad-leaved Xeranthemum*—*Narrow-leaved Xeranthemum*—*Trailing Xeranthemum*.

Yucca, *Adam's Needle*, containing *Common Adam's Needle*—*Thready-leaved Adam's Needle*—*Aloe-leaved Yucca*—*Dragon Tree-leaved Yucca*.

Zygophyllum, *Bean Caper*, containing *Sessile-leaved Bean Caper*—*Purslane-leaved Bean Caper*.

UNDER-SHRUBBY KIND.

Dracocephalum, *Dracocephalum*, containing *Canary Dracocephalum*, or *Balm of Gilead*.

Gnaphalium, *Gnaphalium*, containing *Oriental Gnaphalium* and varieties—*Sweet-scented Gnaphalium*.

Inula, *Inula*.

Keggelaria, *Keggelaria*, containing *African Keggelaria*.

Lavateria, *Lavateria*, containing *Cape Lavateria*.

Lavendula, *Lavender*, containing *Cut-leaved Canary Lavender*.

Lotus, *Bird's-foot Trefoil*, containing *Cretan Silvery Lotus*—*Lotus Jacobæus*—*Upright Lotus*.

Mediola, *Mediola*, containing *Climbing African Mediola*.

Origanum, *Origany*, containing *Dittany of Crete*—*Dittany of Mount Sipylus*—*Cretan Marjoram*—*Origany of Smyrna*.

Periploca, *Virginian Silk*, containing *African Hoary Climbing Periploca*, and varieties.

Phylica, *Bastard Alaternus*, containing *Box-leaved Phylica*—*Heath-leaved Phylica*.

Phyllis, *Bastard Hare's-ear*, or *Simpla nobla*.

Polium, or *Mountain Poly*, containing *Marum*, or *Syrian Mastich*.

Rhamnus, *Buckthorn*, containing *Broad-leaved Indian Rhamnus*—*Zizyphus*, or *Jujube*.

Selago, *Selago*, containing *Corymb Selago*.

Smilax, *Rough Bindweed*, containing *Chinese Rough Bindweed*, or *China-Root*—*Laurel-leaved Rough Bindweed*, and several varieties of each.

Stœbe, *Stœbe*, containing *Bastard Elichrysum*.

These sorts of plants must constantly be kept in pots, or some large sorts in tubs, for moving into shelter in winter, and into the open air in summer; as, being all exotics from various warm parts of the world, they are of tender growth in this climate, and consequently not able to live in the open air in the winter.

The pots and tubs for containing them must be of different sizes, according to the size and nature of the plants, which, as they advance in growth, should have larger pots, &c. accordingly; and when they become too large for the pots, they must be shifted into tubs hooped with iron, with two iron handles to each at top.

And in potting or planting the different sorts, care should be taken that the pots or tubs have holes at bottom for the discharge of redundant moisture; each hole being covered with a piece of tile or oyster-shell before the mould is put in, to prevent their being stopped up, and the earth from being washed out.

The modes of propagating the different sorts, the nature of the earth in which they succeed best, and the season of raising them, are fully explained under the culture of the respective kinds.

General Management of Green-House Plants.

As most plants of this sort are capable of bearing the open air from the latter end of May till October; but the rest of the year demand the protection of the green-house, they of course require to be set out as soon as the weather begins to be suitable, in the spring and summer months; especially for such as all the varieties of Myrtles, Geraniums, Oleanders, Cistuses, Phlomis, Shrubby Aster, Tree-Wormwood, Tree-Candy-tuft, Yellow Indian and Spanish Jasmines, Indian Bay, &c. And this should be done in the last week in May or first in June, according as the season proves more or less favourable for all the other sorts: but it should not be attempted until the season is become perfectly settled, and there is a fair prospect of summer being arrived, as there are often very cold nights, and frequently frosty mornings, in May, and even in the beginning of June, which, if the plants were fully exposed, would pinch the ends of their young shoots and leaves, and greatly injure them. A mild warm day should be chosen for this work; and if a warm rain, it will be of much advantage, as it washes the leaves and branches from the dust they have contracted, and greatly refreshes the plants.

Setting out the Plants.—This is done in the more hardy sorts in their pots, about the middle of May.

When first brought out, it is proper to place them in some sheltered sunny place, for a fortnight, till they are inured to the open air; then to set them in any open exposure, where they

are to remain for the summer. And as soon as they are brought out, they should be cleared from all dead leaves, and all dead wood; and the earth on the surface of the pots be stirred, taking a little of the old out, and adding some fresh mould in its stead, which will prove very beneficial; then give a moderate watering, not only to the mould, but also all over the heads of the plants, to clean them effectually from all dirt and filth which they may have contracted in the green-house.

They may be placed according to the fancy of the proprietor; some of the handsomest plants being occasionally placed to adorn spacious fore-courts, or arranged on each side of large walks contiguous to the main habitation; and others near ornamental garden-buildings; they are also sometimes disposed in groups or small clumps in the most conspicuous places, in different parts of the pleasure-ground; exhibiting different sorts in each group, to cause the greater variety and effect.

When thus placed out, their chief culture is, to supply them plentifully with water during that season in hot dry weather: all the woody or shrubby kinds in particular, likewise the herbaceous kinds that are not very succulent, require it three times a week at least; and in a very hot dry time, once every day. The succulent kinds must also have a moderate supply of water two or three times a week in dry weather; the proper time for watering all the sorts at this season is, either in a morning before nine o'clock, or in the afternoon about four or five; for, if performed in the middle of the day in summer weather, the sun would exhale a great part of the moisture before it effected its intended operation on the fibres of the plants: this business should be duly attended to in dry weather. As the mould, roots, and fibres of the plants are circumscribed within the narrow limits of a pot or tub, the earth, as well as the fibres, dries very fast in summer, and necessarily requires frequent refreshments of water, to preserve that due and constant degree of moisture which is requisite for the support of healthy vegetation.

Moderate rains should not prevent watering occasionally, especially such plants as have spreading heads, which prevents the rains, unless very heavy or constant, from falling in sufficient quantities on the earth of the pots, to moisten it properly. And in hot weather, if some mowings of short grass are spread on the surface of the Orange-tree tubs, and others, it will greatly preserve the moisture. During this season, it will also be a good practice to loosen the surface of the earth now and then, in such pots and tubs as have a tendency to bind or become stiff.

Taking in the Plants.—In the beginning of the autumn, as towards the latter end of September, the more tender kinds of these exotic plants must be removed into the house; the succulent tribe, in particular, should be removed to shelter at the first approach of excessive wet, and cold nights. The oranges, lemons, and all the other species, should be moved into shelter in due time, either in the end of September or early in October; for, if they are permitted to remain in the open air till attacked by sharp weather, it changes the beautiful verdure of their leaves to a rusty yellow hue, which they do not recover during winter: therefore, about the latter end of September, or beginning of October at latest, the principal plants should be brought in: the succulent, and others of the more tender temperature, as early in the former month as the cold weather begins to come on; and continue moving in all the others as the cold increases; and by the middle of October, have the whole collection in. As the time approaches for moving in the different sorts, clear them perfectly well from decayed leaves, &c. all the pots being well cleaned, and loosen the surface of the earth in each pot, adding a little fresh mould. As the different sorts are brought occasionally into the green-house, they may be placed promiscuously, till the whole are in, and then be arranged regularly, as they are to remain for the winter; leaving all the windows quite open till that time. When the whole is brought in, they should be disposed in regular order, so as to appear to the best advantage, both in respect to their general arrangement and variety, and so as each may have an equal portion of sun and air: the tallest plants being arranged in the back, the others in their several ranks, according to their degrees of height, gradually down to the lowest in front; and as there is a vast variety, both in size, shape, and colour of the foliage, they should be so disposed as to set off each other, and give a pleasing variety to the whole; and, if possible, they should stand clear of one another; by which each plant will be separately conspicuous, and the whole exhibit a greater air of freedom and variety, as well as admit an equal portion of sun, and a more free circulation of air.

After the plants have been thus collected in, their principal culture is, the supplying them with fresh air at all opportunities in mild weather, and giving moderate waterings occasionally, picking off decayed leaves, cutting out casual decayed shoots, and making occasional moderate fires in severe weather, also sometimes to dispel great damps and noxious fogs.

In respect to giving air, it should be admitted every mild, calm day, by opening the windows more or less, according to the temperature of the

weather. When the plants are first housed, they should have as much free air as the nature of the season will admit, by opening the windows every mild day to their full extent; and if the air is quite temperate, they may remain open on nights for the first week; but in cold nights they should be constantly shut: this work of admitting air must be constantly attended to all winter; for, without a due portion of this essential article in mild weather, the plants soon lose their fine verdure, and assume a sickly yellowish colour, become diseased, and the young shoots, in many sorts, grow mouldy and rot off, and the leaves of the plants drop; therefore, never omit, every mild day, when not very damp or foggy, to open some or all of the windows, little or much, according as the air is more or less temperate: the proper time during winter, for this, is from about eight, nine, or ten in a morning, till three, four, or five in the evening, according to the mildness of the day: but as the days lengthen, and the warm weather increases, give more air in proportion, earlier and later in the day, as may be judged proper, being careful always to shut all close in due time every evening, as soon as the sharp air approaches. In foggy weather it is advisable to keep the windows quite close; for the great damps occasioned by fogs are very pernicious to these plants whilst they are confined in the house: also, when boisterous or cold cutting winds blow towards the front of the Green-house, the whole should be kept shut; or only, if thought necessary, some of the upper sashes drawn down a little way at top, above the reach of the wind rushing immediately upon the plants: likewise, in all frosty weather, the house should be kept close, except the frost is moderate, and the middle of the day sunny and warm, when some of the windows may be opened a little, but shut close again if the sun is clouded, and at any rate before the air changes cold: in severe weather, the shutters, &c. should be shut every night, also occasionally on days when the frost is extremely rigorous, and no sun: and likewise, in such weather, the assistance of fire-heat, as hereafter directed may be necessary. As the spring approaches, and the weather grows warmer, enlarge the portion of air accordingly, admitting it also both earlier in a morning and later in the evening as the days lengthen; for then the plants will begin to assume a growing state, and a considerable portion of air is requisite every mild day, both to strengthen the new shoots and inure the plants by degrees to the air, against the time for removing them into it fully again for the summer season.

Watering will also be necessary to most of the sorts, but must be afforded them as sparingly as possible during the winter months, and scarcely any should be given when the house is obliged to be shut close through the severity of the weather: there are no certain rules to be given for the application of this; some plants require only a little water once a week, or ten or twelve days in mild weather, such as the orange- and lemon-trees, myrtles, oleanders, shrubby-geraniums, and other woody kinds; all that is necessary being just to preserve the earth very moderately moist; the pots and tubs must therefore be examined with proper attention, and water given to such only as are in want. The herbaceous kinds should be rather more sparingly watered than the shrubby sorts; and all the succulent tribe have water but seldom, some not oftener than once a fortnight or three weeks, and that always but very sparingly at each time; and some that are very succulent require but very little from November till March: indeed all the succulents should only have it now and then at this season, when the earth in the pots becomes very dry.

In performing the watering in general, be particularly careful to do it with great moderation whilst the plants are in the green-house; as, if you once over-wet the earth at this season, it will remain so for a long time, and, by chilling the tender fibres of the roots, often prove the loss of the leaves of many of the plants, and even the death of some sorts. On a sunny day, from about eleven to two o'clock, is the proper time for performing this business.

Soft water, if possible, should be used, or at least such as has been exposed to the air two or three days.

During frosty weather great attention is requisite to keep all the windows close, night and day, unless when very moderate, as just observed, and the middle of the day is sunny and warm; when some part of the house may be opened a little for two or three hours, having particular regard to shutting all close in due time in the afternoon, before the air changes to become sharply cold; and in very severe frosts it must be kept close night and day; and the shutters, or other covers of canvass or mats, be also used every night; also occasionally in the day-time, when the weather is intensely severe, and no sun appears, and there are no fires for fires to keep out the frost. The shutters or other shelters, besides the glasses, should however be used as little as possible in the day-time, except in cases of particular necessity, as every opportunity ought to be taken for the admission of light and fresh air, as much as the tempera-

ture of the weather will possibly admit, as most of the plants only want protection from frost and the common shelter of the house, which with shutting the sashes close every night will be sufficient.

Where there are flues for fires, it will be advisable to make moderate ones at such times as the frost cannot be otherwise kept out, especially on nights; but this must by no means be continued longer than is necessary to guard against very severe frosts.

In very cold, foggy, damp weather, a moderate fire now and then in the flues also proves very beneficial in expelling the damp unwholesome vapours, so pernicious to all plants of this nature.

Whilst the plants are in the house, all decayed leaves, &c. should be constantly picked off, being necessary both to preserve the beauty and health of the plants. The decayed leaves of the succulent kinds should be cut off close with a sharp knife; the plants in general should likewise be occasionally cleaned from any filth they may contract in the house, such as dust, cobwebs, &c.

General Culture of the Plants.—This sort of plants generally want shifting into larger pots and fresh earth as they advance in growth; such as are fast growers, as some of the shrubby geraniums, &c. annually, or every other year; and some plants in large pots, &c. once in two or three years, and others not so often, especially some large grown American aloes, orange- and lemon- trees, and those in large tubs, having a considerable substance of earth about the roots. Sometimes these and other similar kinds, when not convenient to shift them, have the top earth, and a little down round the sides, loosened to some moderate depth in the spring, removing the loosened soil, and filling the space up with fresh compost. But as the plants in general increase considerably in proportion to their nature of growth, shifting into larger pots or tubs, with some fresh earth, should not be omitted occasionally as it may seem necessary, as it proves beneficial to most of the sorts. They may most of them be shifted with the ball of earth about their roots entire; but others, that are rather weak and sickly, require shifting into entire fresh earth.

The most proper time for shifting all the sorts is in April, or before they are removed into the open air for the summer; but it may be occasionally done in autumn, as in August, or the beginning of September, in time to strike fresh root before winter. In the work of shifting, each plant should be drawn out of its pot or tub with the ball of earth about its roots entire, then

all the dry matted fibres round the outside of the ball pared off and cleared away, also some of the old earth at the sides, bottoms, and tops: then having the new pots and fresh earth ready, the holes at the bottoms of the pots should be covered with pieces of tiles or oyster-shells, and some of the fresh earth put in; placing the plant in the pot, and filling up the vacancy all around with more fresh compost, bringing it an inch over the top of the ball, giving a good watering, to settle the earth close in every part: after this it is necessary to place the plants to have shade from the mid-day sun for a week or fortnight.

Such plants as are become of a weak sickly nature should, at shifting, have all the earth taken clean from about their roots, having them washed, and then planted into entire fresh earth.

The larger sorts of plants, such as the orange-trees, lemons, citrons, American aloes, and others of similar growth, should be shifted, when large, from pots into tubs hooped with iron, having two iron handles at top for the convenience of lifting them in and out of the green-house, as they sometimes grow to so large a size as to require two, and sometimes three or four, men to move them.

All such plants as are not shifted annually should, in spring, have the earth in the tops of the pots or tubs loosened to a little depth, also a little way down round the sides, taking the loosened earth out; and in its stead adding a quantity of fresh mould, giving it directly a little water to settle it close. This should never be omitted.

At any time when the surface of the earth is observed to be stiff, whether in the shifted or unshifted plants, it is of much service to stir it an inch in depth occasionally, and add a little fresh compost when necessary.

The mould or compost into which the plants are to be shifted is of considerable importance. The best is obtained from commons where sheep and cattle pasture, particularly in low places, where the finest grass grows, and the soil is deepest. A foot of the top soil with the turf should be taken off, and if a sandy or hazel loam it will do alone; but if a strong loam, some sand and black peaty or moorish soil should be added. Such soils should be laid in a heap six winter months or more, and frequently turned over. Some plants, as aloes, mesembryanthemums, ixias, and exotic liliaceous plants in general, require a soil which is a degree lighter, and which does not retain the water, but lets it pass readily. A little coal-ashes at the bottom of each pot is useful in this view.

Most of the ericas, or heaths, and other beautiful plants from the Cape of Good Hope, from America and Botany Bay, delight and flourish in that sort of earth which comes nearest to their native soil: thus, the heaths like a black peat or moorish soil; and the others, that which is made a degree stronger with loamy earth.

Keep the heads and every part clean from dust and other filth, by occasionally washing with water in all the sorts, which in most is done by waterings over their heads; but in others, when very foul, by washing their leaves with a sponge and water, especially in winter. This is often necessary to the oranges and lemons, and other large-leaved kinds of plants.

When the heads of any of the shrubby kinds are become very irregular or shabby, the branches may be pruned, shorter or longer as necessary, in the early spring.

And where any of the principal exotics assume a declining state, such as oranges, lemons, &c. or have thin, straggling, weakly heads, or are apt to drop their leaves, it is proper either to shift them wholly, or apply some fresh earth to their roots, and then prune the heads moderately close in the early spring, plunging them in a bark-pit under glasses. The heat of the bark-bed so greatly revives their growth, that they break forth into many strong new shoots, and form handsome renewed full heads in the summer.

While in the green-house, some plants drop all their leaves, either by the effects of cold, or over-watering, or sometimes by being kept long in too dry a state, as frequently occurs in myrtles and geraniums, and sometimes oranges, lemons, and others; in which case, it is proper in the spring to prune the heads, shortening the long strong shoots and branches, and to shift them with balls into fresh earth, or, if not shifted, to loosen the earth in the tops and sides of the pots, drawing out the loosened mould, and supplying the place with fresh. They afterwards soon push forth into young shoots and leaves, and renew their heads with verdure. Sometimes myrtles, geraniums, &c. in this state, when headed, may, on being brought forth in the summer, be drawn out of the pots, and plunged in the ground in a sheltered situation, and watered in dry weather; when they will send their roots into the full earth, and break forth strongly at top into young wood and foliage, and form full heads, being then re-potted with balls of earth to the roots.

The heads of green-house plants should never be clipped with garden-shears, nor, by any mode of pruning, trimmed into any

formal figure, as sometimes practised; but every sort be let assume its own natural growth, only just using the knife to regulate any very irregular or rambling shoot or branch, or to thin out some where too much crowded, and to cut out the dead wood they may contain.

GREWIA, a genus containing plants of the tender shrubby kind for the green-house.

It belongs to the class and order *Gynandria Polyandria*, and ranks in the natural order of *Columniferae*.

The characters are: that the calyx is a five-leaved perianthium: leaflets lanceolate, upright, leathery, coloured within, spreading, deciduous: the corolla has five petals, the same form with the calyx, often smaller, emarginate at the base: the nectary a scale inserted into each petal at the base, thickish, bent in, inclined to a rim surrounding the style: the stamina have very numerous filaments, the length of the petals, bristle-shaped, inserted into the base of the germ: anthers roundish: the pistillum is a pedicelled germ, roundish, sitting on a columnar, upright receptacle, surrounded by a five-cornered rim: style filiform, the length of the stamens: stigma obtuse, four-cleft: the pericarpium is four-lobed, four-celled: the seeds solitary, globular, and one-celled.

The species cultivated are: 1. *G. occidentalis*, Elm-leaved Grewia; 2. *G. orientalis*, Oriental Grewia.

The first grows to the height of ten or twelve feet, and has a stem and branches very like those of the small-leaved elm, the bark being smooth, and of the same colour as that of elm when young: the leaves are also very like those of the elm, and fall off in winter: the flowers are produced singly along the young branches from the axils, and are of a bright purple colour; they appear towards the end of July, and continue through August to the beginning of September, but are never succeeded by fruit in this climate.

The second species, in its native situation, is a tree of a middling size: the leaves serrate, petioled: peduncles from the axils, tomentose, trifid, three-flowered: berry sub-globular, depressed, becoming obtusely four-cornered in drying, succulent; the skin, when fresh, saffron-coloured, villose; flesh pulpy, fugacious; stones hard, like grape-stones, having a deep furrow on the back, two-celled. It is a native of the East Indies, flowering in July and August.

Culture.—These plants are capable of being increased by cuttings or layers.

In the first method the cuttings should be made in the early spring, and planted in pots

filled with earth of the light soft loamy kind, being plunged in a bark hot-bed, and well shaded and watered. When they have taken root, they should be gradually inured to the full air, in order to be placed in a warm situation in it till the autumn, when they must be protected in the green-house.

The layers may be laid down in the early spring, and when they have stricken good root be taken off, and planted out in separate pots in the same manner as the cuttings, and afterwards managed in the same way.

The proper periods of removing these plants are the early spring and autumn.

They require little water in the winter season; but in the summer frequent waterings are necessary, as two or three in the course of the week.

They afford ornament and variety among other potted plants.

GROVE, a sort of avenue formed by trees of stately growth, disposed in rows, in grass-grounds, gardens, and parks, on or contiguous to spacious lawns, &c. designed for ornament, shade, and shelter. These sorts of walks are much less in estimation at present than formerly.

In extensive gardens or grounds they may be formed in different parts; a large one contiguous to the dwelling, where it may be conspicuous, is often proper, both to effect ornament, and that it may afford convenient shade for occasional walking in the heat of summer; others may be stationed more remote, on the boundaries of lawns or other open spaces of grass-ground, and near garden buildings, such as summer-houses, temples, and other structures; as, wherever they are situated, they always exhibit an air of grandeur, and are great ornaments to spacious gardens. Such gardens are indeed incomplete without one or more of such plantations.

The trees in forming groves are usually disposed in several straight rows, and at such distances as their branches may so far approach each other, as to afford a moderate shade from the summer's sun; yet so distant, that each tree may have full scope to spread its branches all around, so as to exhibit their straight trunks and spreading heads distinct, according to their natural growth, and that a due portion of air and light may be admitted to promote the growth of the grass between and under them, so as to form a close, firm sward, and constant verdure. They are also sometimes formed with the trees placed irregularly, and the spaces between planted with various sorts of shrubs to form un-

derwood, and with serpentine gravel-walks variously winding through the whole. The trees and shrubs that are most proper for this use, are those of the deciduous and evergreen tall-growing kinds, which form handsome heads.

They are distinguished into two sorts, *open groves* and *close groves*.

For the first sort, the handsomest growing ornamental forest-trees with the most spreading heads should be chosen, and disposed in ranges from fifteen to twenty or thirty feet wide, and the same distance between the trees in each row, that each tree may have full scope to form a spreading head, and so as to admit of the growth of grass under them without injury. Where a shady grove is required to be formed as soon as possible, it may be planted contiguous, but distinct from the above, arranging the rows only at ten or fifteen feet distance; by which it will afford shade several years sooner than the other; and, as exhibiting a more dark and gloomy shade, will afford the greater variety in contrast with it. Open groves, chiefly for shade, may also be formed by disposing all the trees irregularly, that they may produce an imitation of a natural grove, and sooner afford a perfect shade and gloominess, which they effect considerably sooner than in straight rows.

The latter sort of groves are formed of large trees, some planted in straight lines, others irregularly disposed, having the ground between them filled with various under-shrubs, and gravel or sand-walks continued through them in winding or serpentine turns; and are sometimes continued round the out-boundaries of pleasure-grounds, parks, &c. as ornamental plantations, and to afford shady and private walking, as well as shelter from the inclemency of cold cutting winds. The various shrubs forming the underwood have a delightful effect in the whole of the walks quite round.

In forming groves in general, it sometimes happens, when gardens or pleasure-grounds are laid out, that large old trees are found growing in a proper situation to constitute a grove, which, if they do not too greatly approach to the habitation, or obstruct any principal prospect or distant view, should be preserved with care; and although they should stand ever so irregularly or close, they may be somewhat regulated by grubbing up the most irregular and ill-formed, or thinning out some, where they form too close a thicket for the design, either for an open or close grove. By proper care in this respect a grove may often be formed in a very short space of time.

GROUNDSEL-TREE. See BACCHARIS.

GUAIAECUM, a genus comprising plants of the exotic tree kind.

It belongs to the class and order *Decandria Monogynia*, and ranks in the natural order of *Gruinales*.

The characters are: that the calyx is a five-leaved perianthium: leaflets ovate-oblong, concave, obtuse, spreading, deciduous: the two outer ones a little smaller: the corolla has five petals, roundish-obovate, obtuse, concave, spreading, longer than the calyx, ending in short claws, inserted into the receptacle: the stamina have subulate filaments, broader at the base, upright, shorter than the corolla, inserted into the receptacle: anthers oblong, finally recurved: the pistillum is a germ, broader above, angular, pedicelled: style short, subulate: stigma simple, acute: the pericarpium has from two to five capsules (five-celled), on very short pedicels, compressed, membranaceous, covered with a pulpy rind, gibbous on the outside, united on the inside, separating when ripe, gaping: the seeds solitary, bony, and oblong.

The species cultivated are: 1. *G. officinale*, Official Guaiacum, or Lignum Vitæ; 2. *G. sanctum*, St. Juan American Lignum Vitæ; 3. *G. Afrum*, African Acute-leaved Guaiacum.

The first, in its native situation, becomes a very large tree, covered with a hard, brittle, brownish bark, not very thick: the wood is firm, solid, and ponderous, appearing very resinous, of a blackish yellow colour within, and of a hot aromatic taste: the smaller branches have an ash-coloured bark. Browne describes it as an evergreen, of a dark gloomy cast, continuing its verdure in the driest seasons, and at times throwing out a great number of blue flowers, which are succeeded by compressed berries of a roundish form. It takes many years to arrive at its full growth.

It is the tree that affords the gum guaiacum, which is obtained by jagging the body of the tree in May. It exudes copiously from the wounds, though gradually; and when a quantity is found accumulated, hardened by exposure to the air and sun, it is gathered, and packed in small kegs. It is a native of the West Indies.

In the second species there are many leaflets placed along the midrib by pairs; they are rounded and obtuse at their ends, but narrow at their base, of the same consistence with those of the first sort, but of a darker green colour. The flowers are produced in loose bunches towards the ends of the branches, of a fine blue colour, and the petals fringed on their edges.

It is sometimes called in the West Indies Bastard Lignum Vitæ.

The third has rigid branches: the leaves are alternate, with eight pairs of leaflets: common petiole edged, jointed, channelled; leaflets ovate-oblong, opposite, quite entire, mucronate, smooth, stiffish, perennial, very slightly shortened at the inner base: the stipules pressed close to the branches, subulate, very small. It is a native of the Cape.

Culture.—These plants are capable of being increased by sowing the seeds obtained from their native situations, in pots filled with light earth, plunging them in the hot-bed. When the plants have acquired some growth, they should be carefully removed into other pots, and be well shaded till they have taken fresh root; when they should have a large portion of free air admitted, and be frequently watered when the season is hot and dry, but little in the winter. They must constantly in the winter have the protection of the hot-house, though the third sort will often succeed in a good greenhouse.

They are propagated with difficulty by layers. They afford variety in collections of the stove and green-house kinds.

GUILANDINA, a genus containing plants of the tree and shrubby exotic kinds.

It belongs to the class and order *Decandria Monogynia*, and ranks in the natural order of *Lomentaceæ*.

The characters are: that the calyx is a one-leaved perianthium (urceolate or pitcher-shaped): tube short, turbinate, permanent, with an oblique mouth: border five-parted, nearly equal, spreading, deciduous: divisions oblong, broader on the outside, and rounded: the two upper ones a little shorter, the lowest a little longer: the corolla has five petals, inserted into the neck of the calyx: the uppermost roundish, concave, ascending, a little shorter; the rest oblong, broader in front, rounded at the tip, reflex-spreading, longer than the calyx, and the two lowest a little longer than the middle ones: the stamina have subulate filaments, thicker at the base, and villose, decumbent, inserted into the neck of the calyx, shorter than the corolla, unequal: the lower ones gradually longer: anthers oblong, affixed to the back: the pistillum is an oblong germ: style filiform, length of the stamens; stigma simple: the pericarpium is a rhomboidal legume, the upper suture convex, from swelling compressed, one-celled, with transverse partitions: the seeds bony, globular-compressed, solitary between the partitions.

The species cultivated are: 1. *G. Bonduc*, Yellow Bonduc, or Nicker-tree; 2. *G. Bondu-*

cella, Gray Bonduc; 3. *G. Moringa*, Smooth Bonduc; 4. *G. dioica*, Hardy Bonduc.

The first has leaves near a foot and half long, composed of six or seven pairs of pinnæ, each of which has as many pairs of leaflets, which are ovate and entire; the principal midrib of the leaf is armed with short, crooked, single thorns, placed irregularly: the stalks are also armed with thorns, which are larger. The stalks at first grow erect, but afterwards twine about the neighbouring trees and shrubs. The flowers are in long axillary spikes, and of a yellow colour. It is a native of both Indies.

The second species differs from the first in having much smaller leaves, set closer together; and below each pair of leaflets two short stiff crooked spines, which are opposite: the flowers are of a deeper yellow, and the seeds are ash-coloured. It makes a good fence, and is a native of the Indies, &c.

The third is a tree, which has a thick root of a softer substance than usual. Trunk of a middling size, from twelve to twenty feet in height, smooth, with an ash-coloured bark: the branches are rather erect: the leaves bipinnate: common petioles two or three feet long, round, smooth, stiff; the partial ones in five or six pairs, horizontal, compressed: leaflets in three pairs, ternate, oblong, entire, smooth, veined: the flowers in racemes, which are long, axillary, round, pubescent, subdivided, many-flowered; the subdivisions branched, directed one way, bent down; under these are minute deciduous scales. They are of a white or pale red colour. It is a native of the East Indies.

The fourth species has an erect stem, thirty feet high or more, dividing into many branches, covered with a very smooth, blueish, ash-coloured bark: the leaflets are oval, very smooth, and entire, alternate. There are male and female flowers on different plants. It is a native of Canada.

Culture.—The three first sorts are increased by sowing the seeds, which in the two first must be previously well soaked in water, in pots filled with light fresh mould, and plunged in the tan hot-bed. When they have attained a little growth, they should be removed into separate pots, and replaced in the tan-bed, due shade being given. They afterwards require the care of tender exotics, being pretty freely watered in hot weather during the summer; but very sparingly in winter. The third sort must however be very sparingly watered at all times.

The fourth species may be raised by planting the cuttings, or making layers in the spring season. It succeeds best in a light dry soil.

The former are proper for affording variety

among tender stove plants; but the last is so hardy as to succeed in the open ground, in the fore parts of beds, clumps, and borders, in warm dry situations.

GUINEA PEPPER. See CAPSICUM.

GUM, a vegetable disease incident to fruit-trees of the stone kind, distinguished by a morbid exudation of gummy matter from the wounded alburnum, or inner bark. It is supposed by Mr. Forsyth to arise from injudicious pruning, from bruises, or any injuries received in the wood or bark, which may happen from strokes of the hammer in nailing, from pinching the shoots by nailing the shreds too tight, or by driving the nails too close to the branches. And it may be occasioned by leaving the foot-stalks of the fruit, or by pruning in summer, and cutting the shoots to short stumps, and by injuries sustained by a careless application of ladders in nailing and gathering the fruit, &c. but it originates more particularly where large limbs have been lopped or broken off. It may be known before the gum itself makes its appearance, by the bark at first becoming of a brownish colour, and gradually growing darker, till at last the gum begins to ooze out like little blisters. As soon as any of these marks are met with, the infected part should be cut out with a sharp instrument, and the composition and powder applied immediately. In doing this, the gum should be cut out perfectly clean. It may be seen oozing out from between the wood and bark, and must be followed till the white clean bark and wood is arrived at. And afterwards, if any gum should make its appearance, it must be scraped off; which is best done when it is moistened with rain, as it can then be scraped off easily without hurting the bark. This business must be performed without delay; otherwise the disease will advance with rapidity, and greatly injure the trees.

Mr. Forsyth recommends, that when trees are hollow they should be examined carefully, to see whether any grubs have entered the bark and wood, which is known by their perforating the bark; and that where there are any, they should be carefully cut out before the composition is applied to the tree.

It has been suggested by the author of the "Philosophy of Gardening," that this exudation may perhaps be prevented from continuing to flow, by binding on the part, previously smoothed by a knife, thin sheet lead, such as tea is wrapped in, in such a manner as to prevent the gum from being dissolved by rain or dew, as its hardening prevents the exudation, and the consequent exhaustion of the tree. A piece of sponge, soft leather, or Indian rub-

ber should be bound on under it till the part is healed. A strong solution of green vitriol in water is likewise supposed capable of being useful, by being applied to the extremities of the exsuding vessels, and thus stimulating them into contraction, and by that means preventing the further discharge of this substance.

The nice application of a piece of fresh bark taken from a similar tree of inferior value, kept on by the elastic pressure of a list bandage, is also suggested as worthy of being made a trial of in the same intention.

H Æ M

HÆMANTHUS, a genus containing plants of the bulbous-rooted herbaceous flowery perennial kind.

It belongs to the class and order *Hexandria Monogynia*, and ranks in the natural order of *Spathaceæ*.

The characters are: that the calyx is a six-leaved involucre, very large, bearing an umbelule: leaflets erect, oblong, permanent: the corolla is monopetalous, erect, six-patted: parts erect, linear: tube very short, and angular: the stamina have six subulate filaments, inserted into the tube, and longer than the corolla: the anthers incumbent, oblong: the pistillum is an inferior germ: the style simple, length of the stamens: the stigma simple: the pericarpium is a roundish three-celled berry: the seeds solitary, and three-cornered.

The species cultivated are: 1. *H. coccineus*, Scarlet Hæmanthus, or Blood-flower, or Lily; 2. *H. punicens*, Waved-leaved Hæmanthus, Blood-flower, or Bastard Dragon; 3. *H. carinatus*, Carinated Cape Hæmanthus.

The first has a large bulbous root, from which in autumn come out two broad flat leaves, of a fleshy consistence, shaped like a tongue, which turn backward on each side, and, spreading flat on the ground, have a singular appearance all the winter; but in the spring they decay. The flowers are produced in autumn, just before the new leaves come out; and are of a bright red colour, in a large cluster, two or three inches from the bulb. It is a native of the Cape.

In the second species the roots are composed of many thick fleshy tubers, forming a head, out of which arises a fleshy spotted stalk, spreading at top into several spear-shaped leaves,

H Æ M

which are waved on their edges. The stalks are a foot high; leaves six or eight inches long, and two broad in the middle. - From the side of the stalk near the ground breaks out a strong fleshy scape, six or eight inches long, with a large cluster of yellowish red flowers at top. The berry is obovate, of a fleshy scarlet colour. It is a native of Africa.

The third has a large bulbous root, sending out three or four leaves, a foot long or more, not flat, but hollowed like the keel of a boat, and more erect than those of the first sort, but not quite so broad: the flowers are of a paler red. It is a native of the Cape.

Culture.—The first and third sorts are raised with difficulty, as off-sets are only sparingly afforded. The off-sets, when procured, should be planted in pots of light loamy mould, as soon as the stems decay, placing them in a dry glass case. When thus taken up, the old roots may remain out of the ground till August, and be then new potted, and placed out till they require protection for the winter.

The second sort is increased by parting the roots, and planting them in pots of light loamy earth in the early spring, before they put forth new stems. This is also the period for re-potting the old roots.

They are likewise all capable of being raised from seeds, especially the second sort, by sowing them in pots of light sandy earth, and plunging them in the bark stove. When the plants are up, they should have air admitted pretty freely; when of some growth being removed into separate pots, and replunged in the hot-bed. When hardened properly, they may be placed in the dry stove.

These plants require the management of other

bulbous-rooted plants, little water being given in the winter season, but pretty frequently in warm weather, and when flowering, with also a pretty free allowance of air.

They are all very ornamental in stove collections.

HÆMATOXYLUM, a genus containing a plant of the exotic tree kind for the stove.

It belongs to the class and order *Decandria Monogynia*, and ranks in the natural order of *Lomentaceæ*.

The characters are: that the calyx is a one-leaved perianthium, coloured: tube very short, pitcher-shaped, fleshy, permanent: border five-parted, spreading, deciduous: parts oblong, blunt; the four upper ones equal, the lowest a little longer than the rest: the corolla has five lanceolate petals, broadest at top, blunt, veined, spreading, nearly equal, inserted into the calyx, and larger than its divisions: the stamina have ten subulate filaments, hairy at bottom on the inside, upright, unequal, scarcely longer than the corolla, inserted into the calyx: anthers oval, small: the pistillum is an oblong sabre-shaped, compressed germ: style capillary, bent at the tip, longer than the stamens: stigma funnel-shaped: the pericarpium is a lanceolate legume, flat, blunt, one-celled, edged on each side with a thickish suture that does not open, opening by the bursting of the valves in the middle longitudinally, and dividing into two unequal boat-shaped parts: the seeds few, oblong, compressed, furrowed, and fixed to one of the sutures.

The only species is *H. Campechianum*, Log-wood, Blood-wood, or Campeche-wood.

In its native situation it rises from sixteen to twenty-four feet high. The stem is generally crooked, and seldom thicker than a man's thigh: the inner bark is red, and the wood hard: the branches are subdivided, flexuose, prickly, round, ash-coloured: the leaves pinnate: petioles alternate, patulous, round, smooth; leaflets four pairs, on very short petiolules, generally obcordate, entire, small, veined, very smooth and shining, spreading in the day time, but at night upright, converging: the flowers are peduncled, numerous, small, pale yellow; on short, scattered, simple, coloured peduncles. It is a native of Campeche, flowering in March and April.

Culture.—This plant is increased, by sowing the seeds procured from its native situation, in pots filled with light earth, plunging them in the bark-bed in the stove. When of a few inches growth, they should be removed into separate pots, and be replunged into the hot-bed. By this means they grow rapidly the first year.

They are, however, very tender, requiring the constant protection of the stove, and daily watering.

These plants afford variety in mixture with others of the stove kind.

HALESIA, a genus containing plants of the hardy deciduous flowering shrubby kinds, Carolina Snow-drop Tree.

It belongs to the class and order *Dodecandria Monogynia*, and ranks in the natural order of *Bicornes*.

The characters are: that the calyx is a one-leaved perianthium, very small superior, four-toothed, permanent: the corolla monopetalous, bell-shaped, ventricose; mouth four-lobed, blunt, patulous: the stamina have twelve filaments (seldom sixteen) subulate, upright, a little shorter than the corolla: anthers oblong, blunt, upright: the pistillum is an oblong, inferior germ: style filiform, longer than the corolla: stigma simple: the pericarpium is a corticated nut, oblong, narrowing to both ends, four-cornered, the corners membranaceous, two-celled (drupe four-celled): the seeds solitary.

The species are: 1. *H. tetraptera*, Four-winged Halesia, or Snow-drop Tree; 2. *H. diptera*, Two-winged Halesia.

The first frequently comes up with two or three stems, from fifteen to twenty feet high, sending out branches towards their tops: the leaves are serrate, sharp-pointed, with the middle depressed, growing alternately on short foot-stalks: the flowers hang in small bunches all along the branches, each germ producing from four to eight or nine; they are of a pure snowy whiteness; and as they blow early in the spring, before the leaves appear, and continue for two or three weeks, make a most elegant appearance: they are succeeded by pretty large four-winged fruit, hanging likewise in bunches, and agreeable to the taste. It is a native of South Carolina; flowering in April and May.

In the second species, the leaves are six times the size of the foregoing, not at all tomentose underneath: the fruit mucronate, with two large wings opposite to each other, and two minute ones. It is a native of Georgia.

Culture.—These plants are capable of being raised by seeds and layers. In the first method, the seed should be sown in pots of light earth, placing them in a situation to have the morning sun, or, what is better, in a mild hot-bed. When the plants are up, which is often long in effecting, they should have air pretty freely admitted in order to harden them, but be sparingly watered. They should afterwards be occasionally protected from bad weather, and, when of sufficient hardy growth, be turned out of the pots, and removed into the situations where they are to remain.

The layers of the young shoots may be laid

down either in the autumn or spring, slitting the part laid into the earth. When well rooted in the following autumn, they may be taken off and planted out in the nursery, to remain till of two or three feet growth, when they may be planted out where they are to remain.

These plants are adapted to the borders and clumps of shrubberies and pleasure-grounds.

HALLERIA, a genus containing a plant of the shrubby evergreen kind for the green-house.

It belongs to the class and order *Didymia Angiospermia*, and ranks in the natural order of *Personatæ*.

The characters are: that the calyx is a one-leaved perianthium, trifid, flat, spreading, very obtuse, permanent: the upper cleft twice as broad as the rest: the corolla is monopetalous, ringent: tube roundish at the base, bent in with a swelling throat: border oblique, upright, four-cleft; the upper cleft a little longer than the others, blunt, emarginate; the side ones shorter, broader, sharper; the lowest very short, very slender, and very sharp: the stamina have four filaments, bristle-shaped, straight, inserted into the tube, longer than the corolla: anthers roundish, twin: the pistillum is an inferior, ovate germ, ending in a style longer than the stamens: stigma simple: the pericarpium is a roundish berry, two-celled: the seeds small, flat, roundish, and winged.

The only species is *H. lucida*, African Fly-Honeysuckle.

It grows to the height of six or eight feet with a woody stem well furnished with branches: the leaves are ovate, serrate, opposite, and continuing green through the year; the flowers come out singly, and are of a red colour; but being intermixed with the leaves, and growing scattering on the branches, are not easily discerned. They come out in June, and the seeds ripen in September. The leaves continue green all the winter. It is native of the Cape; flowering from June to August.

Culture.—This plant may be propagated by cuttings, which should be planted in pots filled with light earth in the summer.

When the plants are up, they may be exposed in the summer, and have plenty of water; and in winter be housed with Myrtles, and other hardy exotic plants, which require much air in mild weather.

They may also be raised by sowing the seeds in pots of light earth, and plunged in the hot-bed, by which means they succeed very well.

They afford variety in green-house collections.

HAMAMELIS, a genus containing a plant of the hardy deciduous shrubby kind.

It belongs to the class and order *Tetrandria*

Digynia, and ranks in the natural order of *Berberides*.

The characters are: that the calyx is a three-leaved involucre, three-flowered: the two inner leaflets roundish, smaller, blunt; the outmost larger, lanceolate: perianthium double: the outer two-leaved, smaller, roundish; the inner four-leaved, upright; the leaflets oblong, blunt, equal: the corolla has four petals, linear, equal, very long, blunt, reflex; nectary of four truncate leaflets, growing to the corolla: the stamina have four filaments, linear, shorter than the calyx: anthers two-horned, bent in: the pistillum is an ovate germ, villose, ending in two styles, which are of the same length with the stamens: stigmas capitate: there is no pericarpium: the seed is an ovate nut, half covered with the calyx, blunt, furrowed on both sides at the tip, having two little horns spreading horizontally, two-celled, two-valved.

The only species is *H. virginica*, Witch-Hazel.

It has a woody stem, from two to three feet high, sending out many slender branches: the leaves are oval, indented on their edges, having great resemblance to those of the Hazel, and placed alternately on the branches: these fall away in autumn, and then the flowers come out in clusters from the joints. It is a native of Virginia.

Culture.—This plant is propagated by seed, and layers made from the young branches.

In the first method, the seed procured from America is sown in an easterly border, half an inch deep; the plants come up the second spring, the ground being kept clean from weeds: when the season proves very dry, moderate waterings should also be given in summer; and when they are two years old, they should be transplanted into nursery rows.

The layers should be laid down in autumn, or early in spring, the young twigs of the last summer's shoots being chosen; giving them a slit at a joint, then laying them in the earth. They will be rooted, and fit to transplant into the nursery by the autumn following. When they have had some growth there, they may be removed to the places where they are to remain.

They afford variety in the shrubbery and other parts of pleasure grounds.

HAND-GLASSES, such glasses as are moved by the hand, and used for placing over, protecting, and forwarding various sorts of plants. In winter, such as young cauliflowers, lettuces, &c. and in raising seedling plants of both these in the spring, as well as several others, in hot-beds, or in warm borders; also small sallading. And they are particularly necessary in the culture of general crops of summer cucumbers, for pla-

cing upon the hot-bed ridges made in April and May, and also occasionally for melon-ridges made in the same season to produce a crop of autumnal fruit. In the flower-garden, pleasure-ground, nursery, green-house, &c. they also prove very useful in propagating, raising, and protecting many kinds of curious plants in their young growth.

They may also be employed in raising many of the tenderer or more curious annual flowers, such as African and French marygolds, chrysanthemums, balsams, ten-weeks stocks, and others of similar kinds, where better contrivances are not at hand. See ANNUAL PLANTS.

They are likewise useful in striking many sorts of small cuttings, pipings, and slips of tender or curious plants, such as myrtles, flowering plants, and other similar kinds.

Hand-glasses are of different kinds and forms. The leaded glasses consist of many small panes of glass worked into lead-work.

They are mostly made square, but sometimes round or octagonal; in all of which, each is formed in an open frame-work of strong window-lead, and sometimes of cast-iron in the same form; but more commonly lead; the lower part being upright, from six to eight or ten inches in depth, and the other hipped off or sloped on each side, narrowing upward, so as to terminate in a point, as it were, at top, having in that part a fixed erect ring handle of the same material; the glass being laid in lead-work, and the joints well brushed over with proper cement, to render the whole wind and water tight.

They are of different dimensions, from twelve or eighteen inches to two feet wide, or more, to suit different purposes; though for general use in kitchen gardens, about eighteen inches width is the most common, and nearly the same in depth in the whole; but some for particular uses are of smaller sizes, as from six or eight to ten or twelve inches width.

When laid in frames of cast-iron, in putty, they are neat, strong, and durable; but heavy, and much more expensive than leaded glasses.

The bell Hand-Glasses are blown at the glass-houses in different places, and are equally eligible, or superior to the leaded glasses in many cases, especially in kitchen-gardens, particularly for the preservation of plants in winter, such as early crops of cauliflowers to stand the winter, lettuces, &c. as well as for hot-bed ridges of cucumbers and melons, in the summer and autumn crops.

These are in dimensions nearly in proportion to that of the larger sizes of leaded glasses, or rather wider below; made in the bell form, having a rough knob at top serving as a handle; they should be made not too high, but flat and

dome-form above, which is more advantageous in promoting a strong growth, and not so liable to draw up the plants, while they receive the benefit of the sun more effectually.

The leaded glasses are superior in this respect, that when any of the glass-work is broken it can be readily mended or replaced by the glazier; but the bell glasses, when much broken, are nearly useless; though, when they are broken into pieces, they may be joined with a cement of strong white lead, and placed under cover till it is thoroughly dry; and then, with care in handling, they may last a long time. As new bell-glasses are more liable to crack by frost, or too hasty moving them, than older ones seasoned to the weather, in using them the first winter in crops of early cauliflowers, &c. great care should be taken in handling them, in lifting them off and on, or raising one side occasionally for the admission of air: the seasoned old sound glasses are in this respect more valuable than the new ones.

The leaded glasses should have wooden frames at the bottom part to rest upon, otherwise they are soon destroyed by their constant contact with the earth.

HARD-BEAM TREE. See *CARPINUS*.

HARE-BELLS. See *HYACINTHUS*.

HARE'S-EAR. See *BUPLEURUM*.

HAWTHORN. See *CRATÆGUS*.

HEATH. See *ERICA*.

HEART'S EASE. See *VIOLA*.

HEDERA, a genus containing plants of the shrubby, climbing, evergreen, and deciduous kinds.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Hederaceæ*.

The characters are: that the calyx is an involucre of a simple umbel, very small, many-toothed: perianthium very small, five-toothed, surrounding the germ: the corolla has five petals, oblong, spreading, with the tips bowed inwards: the stamina have five subulate filaments, upright, of the same length with the corolla: anthers trifid at the base, incumbent: the pistillum is a turbinate germ, surrounded by the receptacle: style simple, very short: stigma simple: the pericarpium is a globular berry, one-celled (five-celled): the seeds five, large, gibbous on one side, angular on the other.

The species are: 1. *H. Helix*, Common Ivy; 2. *H. capitata*, Cluster-flowered Ivy; 3. *H. quinquefolia*, Five-leaved Ivy.

The first is a parasitical shrub, which by the support of walls, buildings, or trees, rises to a very great height, insinuating itself by a great abundance of fibres into the joints of walls, or

the bark of trees. If no support is near, the stalks trail upon the ground, taking root their whole length, so that they cover the surface closely, and are difficult to eradicate; for, where any small parts of the stalks are left, they will soon spread and multiply. Whilst Ivy is fixed to any support, or trails upon the ground, the stalks are slender and flexible; but when it has reached to the top of its support, they shorten and become woody, forming themselves into large bushy heads; their leaves are larger, more of an oval shape, and not divided into lobes like the lower leaves. While the stalks trail, Ivy does not produce any flowers; and in this state is called *Barren* or *Creeping Ivy*: but when the branches get above their support, they produce flowers at the end of every shoot; these are succeeded by berries, formed into round bunches, and turning black before they are ripe. In this state it is called *Climbing* or *Berried Ivy*. The trunk, in old trees, is covered with an ash-coloured chopped bark; in the young branches it is of a green or purple colour. The leaves are alternate, evergreen, glossy, smooth, while the plant creeps, three-lobed, or sometimes five-lobed; but when it quits its support, ovate: they are sometimes tinged with red, sometimes painted with white veins, particularly in the young branches: the petioles are long, and dilated at the base: the flowers are yellowish, or greenish white, in a very close, thick umbel, at the extremities of the twigs: the berry is placed below the receptacle of the flower. It is found wild all over Europe.

It is observed by Mr. Curtis, that few are acquainted with the beauty of Ivy when suffered to run up a stake, and at length to form itself into a standard; the singular complication of its branches, and the vivid hue of its leaves, give it, he says, one of the first places amongst ever-greens in a shrubbery.

There are varieties with silver-striped leaves, and with yellowish leaves on the tops of the branches.

The second species has the stem arborescent, eight feet high in the stove, erect, cylindrical, abruptly branched. The bark brown, a little cracked. The branches curved upwards, leafy, terminated by flowers. The leaves scattered, more crowded towards the tops of the branches, on foot-stalks, wide spreading, pointed, waved on the margin, very smooth, obscurely three-nerved, veiny, bright green. The foot-stalks various in length, nearly cylindrical, smooth, firmly fixed to the branch by an enlarged triangular base. Buds consisting of several large, roundish, smooth, yellowish scales, soon falling off, which are often tipped with the rudiments

of a leaf, and appear like abortive leaves. Racemes erect, branches generally alternate, ending in little round heads of many sessile flowers. The flowers numerous, white, so small that the structure is not readily to be understood. It is a native of Martinico.

The third has long slender shrubby rooting stems, climbing upon support to a very great height, by their fixing themselves in the walls as they advance. The leaves are quinque-foliate and deciduous, being composed of five oval, serrated lobes, closely covering the stems and branches, changing in the autumn to a reddish cast.

It has been chiefly employed to cover walls or high buildings, which it does in a short time, as it will shoot almost twenty feet in one year; but as the leaves fall off in autumn, and are late before they come out in the spring, it is not much esteemed. As it is not injured by smoke, or closeness of air, it is proper to cover buildings in great towns. It is a native of America.

Culture.—All these plants are readily increased by their trailing branches, which throw out roots their whole length.

They may also be raised by planting cuttings of the young branches in the autumn, on a shady border, which, when they have stricken root, should in the following autumn be removed to where they are to remain.

They are likewise capable of being procured by sowing the seed when perfectly ripe in the early spring, in a moist shady situation.

In training them against walls, &c. it is only necessary to direct a few of the branches at first, as they soon attach themselves to them.

These plants are capable of being employed by way of ornament in various situations.

HEDGE, a sort of fence employed occasionally both for use and ornament in gardens, as for inclosing and dividing the internal parts of the ground.

Fences of this sort are of two kinds, dead and living; but it is only the latter sort that is made use of in gardens. They are the cheapest and most ornamental that can be employed where walls, &c. are not necessary for wall-trees.

There are a great variety of shrub- and tree-plants, both of the deciduous and evergreen kinds, that may be occasionally employed for hedges; the principal of which are, in the first sort—White-thorn, Black-thorn, Crab-tree, Alder, Elder, Poplar, Willow, Hornbeam, Beech, Elm, Lime, Privet, Berberry, Sweet-brier, Rose, Syringa, and Honey-suckle.

In the latter kind—Holly, Yew, Furze, Lau-

rel, Laurustinus, Phillyrea, Alaternus, Box, Evergreen Oak, Evergreen Privet, Juniper, Virginia Cedar, Savin, Rosemary, Pyracantha, and Sea Purslain Shrub, &c.

Outside Hedges.—For this purpose the White-thorn plant forms the best, which, by being properly trained, by trimming or clipping annually, is rendered quite close, hardy, and durable.

Hedges of this sort are formed by planting young plants or sets raised from seed in the nursery, which when a year or two old, or as big as a goose-quill, up to the size of the little finger, are proper for this use. See CRATÆGUS.

The Black or Sloe-thorn is also proper for Hedges, and forms a very strong durable fence; but by its producing such abundance of suckers from the root, it is less esteemed; and as it is well armed with thorns, and of quick growth, it may be useful where the White-thorn cannot be procured.

Hedges of this nature may be raised by sowing or setting the seed or sloes in autumn, when fully ripened, in one or two small drills or trenches, where the hedge is to be, at the distance of five or six inches or more from each other, and to the depth of two or three inches. Where there are two rows, they may be about six or eight inches apart.

But it is a better method to first raise the plants in the nursery till of a proper size, as two years old, and then plant them out in rows as above.

The Crab-tree, of the apple, as well as thorny sort, are sometimes planted for Hedges; but the plants for this purpose should be such as are raised from the kernels of the wild crabs, which come up more thorny than those of the cultivated kinds, and shoot more branchy and close, quite from the bottom. These should, however, only be made use of as being of quick growth, and where the others cannot be procured.

Hedges of these may either be raised by sowing the kernels of the fruit in autumn or winter, in the place where the Hedge is intended, in drills the whole length, an inch deep, covering them that depth with earth; or the plants raised first from seed in the nursery, which, when a year or two old, may be planted out. Some plants of the Hedge may, in this case, be suffered to grow up, and afford an annual crop of crabs for verjuice. A proper number of the plants may likewise be used, as they stand in the Hedge, for stocks, to graft on with useful family or cyder apples.

The Elder plant is also used for outward Hedges where a fence is wanted as soon as pos-

sible, as being very expeditious in its growth, though not the most beautiful. Hedges are readily formed by planting large truncheons, or cuttings of the straightest upright shoots and branches, from two or three to six feet long, planted either upright a foot distance, and wattled along the top to preserve them firm and even; or placed slanting across one another chequer-wise, forming a sort of lattice-work, which is the most effectual method. In either way of planting, the lower ends of the cuttings must be sharpened, making holes to receive them fifteen or eighteen inches deep, either in the level ground, or the sides or tops of the banks.

The Alder is also proper to plant for Hedges in wet or marshy ground, as being an aquatic, and growing readily by small or large cuttings like the Elder.

It is very proper on the borders of rivers, brooks, or other waters, as its roots, and numerous suckers arising from their lower parts, form such a close thicket as effectually to preserve the earth of the banks from being undermined and washed down.

The Lombardy Poplar, as emitting numerous side-branches quite from the bottom, and being of very quick growth, is also occasionally employed to form an expeditious outward Hedge along the side or top of a bank or ditch, or to train as a loftier Hedge for shelter, shade, blind, &c.

Hedges of this plant are formed at once, if wanted, of five or six feet or more in height, by having young trees, well branched from the bottom, heading the top to the above height, and planting them in a single row a foot or two asunder. Younger sets of two or three feet in height may be planted and trained. When designed as an outward Hedge, they should generally have an outside ditch. They may be kept to an orderly thick growth, by proper clipping in the summer season.

The Willow is also sometimes planted to form outward Hedges along the sides of watery ditches, brooks, rivulets, &c. or any marshy or moist situation. They are planted either by small cuttings, or larger long sets of several feet, and inserted in the manner directed for the elder cuttings, so as to form an immediate Hedge. In either method they run up quickly, and may be kept close and regular by proper cutting in the summer season.

The Holly forms an excellent and beautiful Hedge. It is the best evergreen Hedge that can be planted for an outward fence, as it grows close, and is well furnished with leaves, which being armed with thorns, no cattle browse upon them; and being always in foliage, it affords

good shelter in winter, and is ornamental at all seasons. The only objection to it is, its slowness of growth the first four or five years.

Hedges of this sort are formed either by sowing the seeds at once in the places where the Hedges are to be, in drills an inch and half deep; or by planting young plants of two or three years old from the nursery: this is rather the best practice. They may be planted in one or two rows: though two rows planted a foot asunder, and the same distance in each row, form the thickest and most effectual hedge. They may be kept in order by clipping once or twice a year.

Yew is occasionally used as a boundary Hedge, and when full grown is very thick and close.

These Hedges should be guarded by a ditch or bank on the outside. They are best raised by setting the young plants.

The Furze plant is sometimes used for an outward evergreen Hedge, but which makes only an indifferent one, being apt to die off in gaps. As it grows well upon dry banks, or any poor dry soil, it may be used for a Hedge in such cases: these are raised by sowing the seeds in autumn at once in the place where it is designed to have the hedge, in drills an inch and a half deep.

In the general management of these Hedges it may be observed that all outward ones, designed as fences, should have a ditch and bank; the ditch, &c. serving as a defence to the young Hedge against cattle, &c. till it is grown up, and afterwards rendering the whole a more effectual outward fence. When planted on the level ground, they should be defended with railings, open pales, hurdles, or a stake and bush dead hedge, till advanced to the above growth. Where a ditch and bank is intended, the ditch on the outside should be three feet wide at top, two or three deep, sloping to one wide at bottom; raising a low bank on the inside on which to set the plants, which may be planted either on the side of the inner bank, in two rows one above the other, a foot asunder, as commonly practised for quick Hedges, putting them in in forming the ditch and bank; or be planted entirely on the top of the bank, first forming the ditch and bank, and levelling the top so as to form a sort of border or bed extending longways, planting the sets in one or two rows the whole length; but two rows a foot asunder is the most eligible for all outward fences, as they always form the thickest, strongest, and most effectual Hedge-fences.

In whichever way the planting is performed, the roots of the sets should always be bedded in,

in the finest loose mellow mould that can be procured. With this care large plants will succeed in the most perfect manner.

Division Hedges.—When Hedges are designed for middle fences to divide grounds, two sided banks are raised a yard high, and as broad at top, having a slight ditch on each side, and each side of the bank formed with square spit-turfs from the adjoining ground, and the middle filled up with mould from the ditches on each side; so that, when finished, it forms a yard-wide bed all the way on the top. Along the middle of these, plant two rows of hedge-sets, or sow the seed in drills as has been directed.

But where no ditch or raised bank is required, the place for the Hedge should be marked out on the level ground, two or three feet broad, digging it along one or two good spades deep. The sets should then be planted in one or two rows, ranging along the middle; or the seeds sown at once where it is intended to have the Hedge, in two drills, a foot asunder, the whole length. For interior garden Hedges one row is generally sufficient, either of sets planted or seeds sown. In this mode, where the sets are of a tolerably large size and strength, it will be proper to form a trench, in which to plant each row, with the roots all a regular depth, and the tops upright; or, if quite small young sets, they may be planted with a dibble.

In the first method, one or two narrow trenches should be formed longways, for a single or double row of sets, with the spade, by cutting out a narrow trench six or eight inches deep all along, for each row of plants, making one side upright; then the sets should be placed in the trench close against the upright side, six, eight, or ten inches asunder in the row, with their tops all upright, several inches above ground; and turn in the earth directly upon the roots, &c. to the depth of the trench, treading the earth there to moderately firm, to fix the plants in the proper position as the work proceeds;—and if intended to plant two rows of sets to form a double Hedge, make another trench a foot distance from the first, and plant the sets in the same manner and distance; placing those of the second trench opposite the interval spaces of the first row of sets, earthing them in regularly as the others, and treading it down close to the sets, evenly along the surface.

In trench-planting, the sets may likewise be put in, by planting them as you proceed in digging the trench; marking out with the spade a foot-wide trench, digging out a spade depth of earth at one end, the width of the trench, then placing a set therein close to one side; or, if intended to have a double Hedge, placing two

sets, one to each side of the trench; and then, in either method, proceeding in digging, turning one or two spades of earth in upon the roots of the sets; and at eight or ten inches from these, plant one or two sets more in the same order, digging and earthing them in as the others; and thus proceed, digging along and planting the row of sets as the work advances; observing in double rows to place the sets opposite to the intervals in the rows of each other.

In planting with the dibble, the ground should be previously well dug over a spade deep; then trimming the straggling roots and tops of the plants, with the dibble make a hole for each set at the above distances, inserting the roots a proper depth, and close the earth well about each set, as planted.

In forming Hedges by sowing the seeds at once in the intended places for the plants to remain, the ground should be properly dug, and then either one drill for a single row, or two for a double Hedge, should be formed, a foot asunder, sowing the seed tolerably thick in them, and covering it an inch or two in depth with the earth. The place should be kept very clear from weeds, both before and after the plants appear; and if the plants are any where too thick, they may be thinned out at the proper season.

All such Hedges as are exposed to cattle, must, as soon as planted, be protected either with a stake and bush Hedge, hurdles, or rails, for four or five years, till they grow up. They should also be duly hoed and weeded while young, and kept very well cleared from all sorts of weeds. This should be particularly attended to the first two years.

And where designed to be trained, they should be annually clipped over in summer, being topped sparingly while young, only just trimming off the tops of the straggling and run-away shoots, to preserve a little regularity, that the whole may advance equally, and promote lateral wood to thicken them as they advance; and cut in moderately on the sides. But when arrived at nearly their proper height, as four, five, or six feet, or more, they may be trimmed in close on the sides and top annually, to preserve them thick and within their proper bounds, cutting the sides always first as even as possible; then the tops, which should also be cut as even as a line; always cutting in nearly to the old wood of the former year's clipping, otherwise the Hedges will get too broad; the tops being always kept narrower than the bottoms.

The neatest mode of cutting them at the tops is that of the ridge form.

Regular Hedges were formerly in great request in gardens: almost all the different com-

partments and divisions of pleasure-grounds were surrounded with them, of various sorts of trees and shrubs, both evergreens and deciduous, which being neatly trained and clipped once or twice annually, sometimes appeared very ornamental; but from their surrounding, shutting out, and obstructing the sight of the different shrubbery borders, clumps, and other parts, as well as their concealing the grounds, and appearing stiff and formal, they are at present little in use. They are only introduced occasionally, either as outward or division fences, or for shelter, shade, &c. in particular compartments, and to cover unsightly objects.

The hedges formed of lofty elm, lime, beech, and some other sorts of deciduous trees, in pleasure-grounds, for ornamental training, are also laid aside, as being stiff, awkward, and troublesome in keeping in order.

The various fancy devices in hedge-work have likewise given way to a better and more easy rural taste.

In addition to what has been said on hedges formed of the more common sorts of plants, it may be observed, that the laurel, though a singularly beautiful evergreen, adorned with a noble large foliage, forming vigorous shoots, never grows so compact, or is so easily kept in form as some other sorts; besides, its leaves being very large, when clipped with shears, they are unavoidably cut through, and so stubbed and mangled as to have a disagreeable appearance. In these hedges, therefore, instead of performing their annual training with shears, the shoots should be trimmed off with a knife, to preserve the leaves entire. This plant is proper to train Hedge-fashion to hide any disagreeable fence, and will grow either under trees, in the shade, or in an open exposure, and is of quick growth.

Hedges of it should be planted in one row, at from eighteen inches to three feet distance, according to the size of the plants at the time of planting them out.

The *Laurustinus*, from its being not only an evergreen, but a beautiful flowering shrub, forms a delightful Hedge for ornament, as it is covered with flowers in winter and spring. It is also well adapted for training hedge-fashion against any shabby fence or naked wall. In either method, it should be planted in one row, at from eighteen inches to three feet distance.

The *Phillyrea* and *Alaternus*, being beautiful evergreens, form very ornamental Hedges. They greatly resemble each other; but the *phillyrea* being the strongest grower, as well as thickest shooter, is the more proper for a hedge: for variety both may be used: they are also good evergreen shrubs for training hedge-fashion

against unsightly or naked walls, or paling fences, as they soon cover them; and if the common green and variegated kinds are intermixed, in either mode of hedge-work, they have a delightful effect.

They should be planted in one row, at from about fifteen or eighteen inches to two or three feet distance between plant and plant.

The Bay is also capable of forming a tolerable evergreen Hedge for variety, and may be led up six or seven feet high; placing the plants half a yard distance.

The Evergreen Oak is likewise a proper plant to form a tall Hedge, as it may be trained fifteen or twenty feet high, if required. It should be planted in one row, setting the plants one, two, or three feet asunder, according to their size or strength.

The Evergreen Privet will also form a handsome good Hedge five or six feet high, by planting the sets a foot asunder, and training it up narrow at top.

The Tree-box makes a very close and beautiful low evergreen hedge, four or five feet high, when the sets are planted about a foot asunder.

The lesser sorts of Evergreens are sometimes employed for variety to form moderate Hedges, from about three or four to five or six feet in height; they should be planted in a row at from twelve or eighteen inches to two feet asunder.

All the sorts of Evergreens are proper for Hedges, when from about twelve or eighteen inches to two or three feet in height; though the Holly succeeds better when planted in its younger growth.

The proper season for planting them is either in autumn or in spring; for it is not safe to transplant evergreens in the middle of winter. Where the soil is moist the latter is the best period; but in dry gravelly soils, the former.

In planting these sorts of evergreens, for middle or internal Hedges, no ditches or banks are necessary as for outward Hedges for fences; so that, in the place where the Hedge is designed, a sort of border should be marked out the whole length, two or three feet wide, and dug or trenched over for the reception of the plants: the plants need only, in these cases, be planted in a single row.

Among the deciduous plants, the Hornbeam forms a beautiful summer Hedge; being a moderate but very close shooter, well furnished with leaves, and capable of being trained up from about six or eight to twelve or fifteen feet high; but the leaves, though they wither in autumn, remaining firmly attached to the branches all winter, make but a shabby appearance at that season. It is, however, on this account superior to most other deciduous Hedges

for the purpose of forming shelter in the winter. For Hedges, it should be planted in single rows, at about half a yard asunder in the plants, to form a close moderate hedge as soon as possible; but if designed to be brought up pretty tall, and the plants are spreading, they should be set about three feet distant.

The Beech also forms a close regular Hedge, from about six or eight to fifteen or twenty feet high: the leaves withering on the branches in autumn, continue dropping off most part of the winter. These plants should be planted in the same manner as the Hornbeam.

The Elm forms a close, even, and beautiful Hedge, and may be trained from six or eight, to ten, twenty, or thirty feet high, forming a close fence from bottom to top. The plants for this purpose may be from three or four, to eight or ten feet or more in height, and should be planted in a single row from two or three, to six or eight feet distant, according as they are less or more spreading, and as wanted to form a close Hedge as soon as possible.

The Lime-tree is sometimes employed for ornamental Hedges for variety, but is much inferior to the other deciduous sorts, as it becomes thin and shabby by clipping, and is thinly leaved.

Other low kinds of shrubs of this sort are sometimes employed for variety: some sorts, such as roses, honeysuckles, and syringas, when formed into low Hedges, besides their property as Hedges, produce great quantities of flowers, and afford a fine fragrance.

The plants for this use are of a proper size when from about one foot to a yard in height, according to the sorts. It is best to plant them young, choosing such as are well furnished with plenty of side or lateral shoots, that they may form a close hedge quite from the bottom. They may all be planted either in autumn or early spring, in open weather.

The method of planting them is nearly the same as in the evergreen kinds.

These sorts of Hedges should be trained and clipped in the same manner as directed above.

In order to keep Hedges in perfect good order, they should be clipped twice every summer: the first time about midsummer, when they have made their summer shoot; and the second clipping towards the middle or latter end of August. But when this is done only once in the summer, the clipping should not be performed until the beginning of August, as when cut sooner they shoot again, and appear almost as rough the remainder of the summer, and all winter, as if it had not been done at all.

HEDGE-CLIPPING MACHINE, a sort of machine-scaffolding, or stage, ten, twenty, or thirty feet high, or more, with platforms at dif-

forest heights, to stand upon, the whole being made to move along upon four low wheels. It is composed of four long poles for uprights, well framed together, eight or ten feet wide at bottom, narrowing gradually to four or five at top, having a platform or stage fixed at every seven or eight feet height, with one near the top, each having a rail waist-high: there is a sort of ladder formed on one side to ascend by, &c. Upon this machine a man or two may be employed on each stage or platform, trimming the hedge with shears, and sometimes with a light garden hedge bill fixed on a handle from three to five or six feet long, which is more expeditious, though it will not make so neat work as cutting with shears. It is very useful in clipping high hedges or trees. And it may be employed for dressing, cleaning, pruning, and nailing different sorts of trees, as well as various other purposes. In extensive pleasure-grounds and gardens they are essentially necessary.

HEDYSARUM, a genus containing plants of the herbaceous flowering kind.

It belongs to the class and order *Diadelphia Decandria*, and ranks in the natural order of *Papilionaceæ*.

The characters are: that the calyx is a one-leafed perianthium, half-five-cleft: clefts subulate, upright, permanent: the corolla is papilionaceous, streaked: banner reflex-compressed, ovate-oblong, emarginate, long: wings oblong, narrower than the other petals, straight: keel straight, compressed, broader outwardly, transversely blunt, from the base to the swelling part bifid: the stamina have diadelphous filaments, (simple and nine-cleft,) bent in at a right angle: anthers roundish, compressed: the pistillum is a slender germ, compressed, linear: style subulate, bent in with the stamens: stigma very simple: the pericarpium is a legume with roundish, compressed joints, two-valved, and containing one seed: the seed kidney-shaped and solitary.

The species chiefly cultivated are: 1. *H. Alagi*, Prickly Hedysarum; 2. *H. Canadense*, Canadian Hedysarum; 3. *H. gyrans*, Sensitive Hedysarum; 4. *H. coronarium*, Common Hedysarum, or French Honeysuckle; 5. *H. flexuosum*, Waved-podded Hedysarum; 6. *H. humile*, Dwarf Hedysarum; 7. *H. spinosissimum*, Prickly Hedysarum.

The first has the stems shrubby, about three feet high, branching out on every side: the leaves are shaped like those of broad-leaved Knot-grass, very smooth, of a pale green colour, on short foot-stalks. Under these come out thorns, near an inch long, of a reddish brown colour. The flowers come out from the side of the branches in small clusters, are of a

purple colour in the middle, and reddish about the rims. It is a native of the Levant.

The second species is an upright plant, and mostly smooth: the stem streaked and angular: the leaflets are lanceolate: the stipules awl-shaped. It is perennial, and a native of Virginia, &c., flowering in July and August.

The third has a branching perennial root (biennial, annual): the stem shrubby, three feet high, wand-like, upright, very smooth, round, without knots: the leaves are alternate, petioled, hanging down or spreading, often vertical, sometimes simple but usually ternate, especially in adult plants: the middle leaflet lanceolate, long, flat, quite entire, very smooth, veined; the side ones very small, and seeming rather to be appendicles than leaflets; they are on short petioles, which are remarkable for a motion peculiar to them. The flowers many and nodding. It is a native of Bengal.

The fourth species has a biennial root: the stems from two to three feet high, hollow, smooth, and branching: the leaves are composed of five or six pairs of oval leaflets, terminated by an odd one: they are alternate, and from the angles which they form with the stem and branches, peduncles come out five or six inches in length, sustaining spikes of beautiful red flowers, which open in June and July, and perfect seeds in September. It is a native of Spain, &c.

There is a variety with white flowers.

The fifth species is annual, and has some resemblance to the foregoing, but is much smaller: the stalks rise near a foot high, and the leaves are composed of two or three pairs of ovate leaflets, terminated by an odd one: the flowers come out in spikes at the top of the stalks, and are of a pale red, intermixed with a little blue. They appear in July, and are succeeded by jointed pods. It is a native of the Levant.

The sixth has a perennial root: the stems half a foot in length, usually with one branch and leaf only: the leaflets obovate-oblong, villose underneath: the spike ovate. It is a native of the South of France, &c., flowering in July and August.

The seventh is an annual plant: the leaflets four or five pairs, with an odd one, narrow and oblong: the stem terminated by small spikes of purple flowers, which are succeeded by small rough legumes. It is a native of Spain, &c.

Culture.—All these plants are capable of being raised by sowing the seeds in the early spring.

In the first sort they should be sown in pots of light earth, and plunged in a moderate hot-bed. When the plants are of some growth they should be removed into separate pots, and be replunged into a very moderate hot-bed, being

 Creeping-rooted Hedyсарum

properly shaded till they are well rooted. They should afterwards be gradually inured to the open air, being protected in winter as there may be occasion.

The seeds are often long in coming up.

In the second sort the seed may be sown in the early spring, as April, on a bed of light fresh earth, or where they are to remain. In the first case they should be removed where they are to grow in the autumn. These plants should not be often removed afterwards.

The third sort is raised in the same manner as the first, and should have free air in the summer, and be protected occasionally in the winter.

The other sorts are all increased in the same manner as the second, being pricked out while young, and in the autumn removed to the places where they are to grow and flower.

As the biennial sorts either decay or dwindle after flowering, they should be raised in fresh supplies every year from seed.

These plants are very ornamental in the beds, borders, clumps, and other parts of pleasure-grounds, and some of them among other potted plants.

HELIANTHUS, a genus containing plants of the hardy herbaceous flowery kinds.

It belongs to the class and order *Syngenesia Polygamia Frustranea*, and ranks in the natural order of *Compositæ Oppositifoliæ*.

The characters are: that the calyx is common imbricate, somewhat squarrose, expanded; scales oblong, broadish at the base, gaping every where at the tips: the corolla compound radiate: corollets hermaphrodite, very numerous in the disk: females fewer, much longer in the ray: proper of the hermaphrodites cylindric, shorter than the common calyx, bellying at the base, orbicular, depressed: border five-toothed, sharp, spreading: of the females ligular, lanceolate, quite entire, very long: the stamina in the hermaphrodites consist of five filaments, curved, inserted below the belly of the corollet, the length of the tube: anther cylindric, tubular: the pistillum in the hermaphrodites is an oblong germ: style filiform, length of the corollet: stigma two-parted, reflex: in the females, germ very small: style and stigma none: there is no pericarpium: unchanged calyx: seeds in the hermaphrodites solitary, oblong, blunt, four-cornered, compressed at the opposite angles; the inner ones narrower, crowned with two lanceolate, acute deciduous chaffs; in the females none: the receptacle chaffy, large, flat: chaffs lanceolate, acute, two separating each seed, deciduous.

The species cultivated are: 1. *H. annuus*, Annual Sun-flower; 2. *H. indicus*, Dwarf Annual Sun-flower; 3. *H. multiflorus*, Perennial

Sun-flower; 4. *H. tuberosus*, Tuberous-rooted Sun-flower, or Jerusalem Artichoke.

There are several other species of the perennial sort that may be cultivated.

The first has an annual root: the stem single or branched, from five or six to ten or fourteen feet in height, and in hot climates twenty or more; when vigorous, the size of a man's arm: the leaves are alternate, a span or a span and a half in length, and almost as much in breadth, rough, serrate, acuminate, hanging down at the end, on long petioles: the flower single (sometimes several), nodding, a foot or more in diameter. It is a native of Mexico, flowering from June to October. Martyn observes, that as to its turning with the sun, it is a vulgar error; Gerarde could never observe it; and he has seen four flowers on the same stem pointing to the four cardinal points.

There are varieties with double flowers, deep yellow, and sulphur-coloured.

The second species is perhaps only a variety of the first, though constant; but the leaves are convex above in the disk, and of a darker green. The peduncles are less thickened at top, or rather of an equal thickness every where, whence the flowers nod less. The scales of the calyx, except the inmost row, grow out into petioled pendulous leaflets. It grows only from eighteen inches to three feet in height. It probably comes from Mexico or Peru.

The third has the stem and peduncles scabrous: the leaves cordate-ovate: the calyxes loosely imbricate, neither squarrose nor drooping, consisting of forty to fifty scales: the stems many, upright, from five or six feet to eight or nine in height, branching, the stem and each branch terminated by a flower, the principal one sometimes nine or ten inches in diameter, the lateral ones gradually smaller: the leaves some opposite, others alternate. There is a constant succession of flowers from July to November.—It is a native of Virginia.

In the fourth species the stems are several, rough, hairy, streaked, from eight, ten, or twelve to sixteen feet in height, the size of a child's arm: the leaves alternate, light green, rough, pointed, eight inches broad, and ten or eleven inches long, deeply serrate, smaller towards the top: the branches many, long, from bottom to top: the flowers terminating, small; florets in the ray twelve or thirteen. These seldom blow before October, and in some seasons they do not expand at all. The seeds never ripen here: the roots creeping, with many tubers clustered together, thirty, forty, or fifty from one plant, measuring a peck, or in good soils half a bushel; they are, like the common potatoe, red on the outside, and very irregular

in their shape, the size of a man's fist in the largest. It is a native of Brazil.

Culture.—All these flowery plants are easily increased, the two first sorts by seeds, and the others by dividing their roots.

The seeds should be sown in the early spring months, in the places where the plants are to grow and flower, in patches of three or four seeds together. When the plants are up they may be thinned out to one or two of the best.

They may be had more forward by sowing them on a moderate hot-bed, under glasses, and afterwards transplanting them to the situations where they are to grow.

The divided roots may be planted out in the places where they are to remain, either in the autumn or the early spring months.

These plants produce a fine ornamental effect in the back parts of the borders, clumps, and other parts of pleasure-grounds, and by sowing at different times may be kept in flower for a considerable length of time.

In the perennial sorts the decayed stems should be cleared away when they begin to decline. They continue long.

The last, or tuberous-rooted sort, is increased by planting the smaller roots, or the larger ones cut in pieces, a bud being preserved to each, either in the spring or autumn, allowing a good distance, as the roots multiply greatly. In the autumn following, when the stems decay, the roots may be taken up for use.

When cultivated for a crop, the sets should be planted in an open part of the kitchen-garden, in rows three feet or more asunder, and at least eighteen inches distant from each other, to the depth of four or five inches. The best time is the latter end of March, in a light soil. The roots may be taken up for use in September, and the whole crop housed in October. When kept in sand in a dry place, they continue the whole winter very good.

HELICONIA, a genus containing a plant of the tall herbaceous perennial kind, for the stove.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Scitamineæ*.

The characters are: that the calyx consists of common and partial spathes, alternate, distinct, with hermaphrodite flowers: there is no perianth: the corolla has three petals, oblong, channelled, erect, acute, equal: nectary two-leaved; one leaflet nearly equal to the petals; the other very short, channelled, hooked, opposite: the stamina consist of five (or six) filaments, filiform: anthers long, erect: the pistillum is an inferior oblong germ: style shorter than the stamens: stigma long, slender, curved, with a terminating head: the pericarpium is an oblong

capsule, truncate, three-sided, three-celled: seeds solitary, oblong.

The species is *H. Bihai*, Bastard or Wild Plantain.

It is a large herbaceous plant, from ten to twelve feet in height: the leaves oblong, narrower at both ends, entire, marked with parallel lines, erect, thick, and very smooth. Petioles the length of the leaves or more, round, thick, channelled above. Scape upright, the length of the petioles, round, thick, smooth: spadix simple, upright: common spathes several (eight to ten), rigid, cordate, embracing, from erect, spreading, acuminate, distich, yellowish brown: the flowers are in bundles concealed within each spathe: partial spathes membranaceous, whitish, the length of the flowers, which are distinct, subsessile, pale or greenish yellow. It is a native of the West Indies, flowering in spring.

Culture.—These plants are increased by suckers arising from the root, particularly after having fruited, which may be taken off any time in summer, with fibres to them, planted in pots, and plunged in the bark-bed, where they will readily grow, and afterwards shifted into larger pots as they advance in height.

They afford variety among other stove-plants.

HELICTERES, a genus containing plants of the shrubby exotic kind, for the stove.

It belongs to the class and order *Gynandria Decandria*, and ranks in the natural order of *Columniferæ*.

The characters are: that the calyx is a one-leaved perianthium, tubulous, half-ovate, obliquely spreading, unequally five-cleft, coriaceous: the corolla has five petals, oblong, equal in breadth, fixed to the receptacle, longer than the calyx: claws long, with a tooth on each side at the base: nectary of five petal-shaped, lanceolate, very small leaflets, covering the germ: the stamina have five, ten, or more filaments, very short: anthers oblong, lateral: the pistillum is a filiform receptacle, very long, bowed back, bearing an ovate germ at the tip: style subulate, longer than the germ: stigma subquincifid: the pericarpium consists of five capsules, often twisted spirally, one-celled: the seeds very many and angular.

The species cultivated are: 1. *H. baruenensis*, Small-fruited Screw-tree; 2. *H. isora*, Great-fruited Screw-tree.

The first is an upright tree, about twelve feet in height, branching but little. The younger branches, peduncles, and petioles are tomentose: the leaves acute, wrinkled, tomentose, and whitish underneath, somewhat hairy on the upper surface, petioled, alternate, deciduous: the stipules awl-shaped: the peduncles many-flowered, terminating, thick: about the pedicels are

large, depressed, green glands, uncertain in number, black when dried. The flowers have no scent. It is a native of the island of Barú.

The second species is likewise a small upright tree, about twelve feet high, branching but little: the younger branches, peduncles, calyxes, and leaves tomentose: the leaves petioled, alternate, acute: the stipules in pairs, bristle-shaped: the peduncles many-flowered, terminating, glandular. It is a native of Jamaica, flowering here in June and July.

Culture.—In these plants the increase is effected by seeds, which must be sown upon a hot-bed in the spring, and when the plants are come up sufficiently strong, they should be each planted in a separate small pot filled with light earth, being plunged into a moderate hot-bed of tan, due shade from the sun being given till they have taken new root. They should afterwards be treated in the same way as other tender shrubs, raising the glasses every day in proportion to the weather, that they may have fresh air. In summer the plants should remain under the frames, if there is sufficient height; but in autumn be replunged into the tan-bed in the stove, where they should always remain, being careful to shift them into larger pots when they require it, and not give them too much wet in the winter. In summer they should have a large share of air in warm weather, and be often refreshed with water.

These plants are very ornamental among other stove exotics.

HELIOTROPIUM, a genus comprising plants of shrubby, herbaceous, annual, and biennial kinds.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Asperifolice*.

The characters are: that the calyx is a one-leaved perianthium, tubular, five-toothed, permanent: the corolla monopetalous, salver-shaped: tube the length of the calyx: border flat, half-five-cleft, obtuse: clefts smaller, alternate, more acute, between the larger ones: throat naked: the stamina have five filaments, very short in the throat: anthers small, covered: the pistillum has four germs: style filiform, length of the stamens: stigma emarginate: there is no pericarpium: calyx erect, unchanged, cherishing the seeds in its bosom (berry): the seeds four, ovate, acuminate (nuts four, naked or corticate, not perforate.)

The species cultivated are: 1. *H. Peruvianum*, Peruvian Turnsole, or Heliotrope; 2. *H. Indicum*, Indian Turnsole, or Heliotrope; 3. *H. parviflorum*, Small-flowered Turnsole, or Heliotrope; 4. *H. Curassavicum*, Glaucous Turnsole, or Heliotrope; 5. *H. Canariense*, Canary Heliotrope.

The first rises with a shrubby stalk from two to three feet high, dividing into many small branches: the leaves are three inches long, and an inch and half broad in the middle, hairy, greatly veined, and ash-coloured on their under side, on short foot-stalks: the flowers are produced at the ends of the branches in short reflex spikes, growing in clusters: the peduncles divide into two or three, and these again into smaller ones, each sustaining a spikelet of pale blue flowers, which have a strong sweet odour. It grows naturally in Peru, flowering here great part of the year.

The second species has an herbaceous stem, a foot and a half or two feet high, round, scabrous, hirsute, subdivided: the leaves cordate-spatulate, ovate, slightly serrate, wrinkled, nerved, hairy, softish: on pretty long petioles, two inches and a half long, and one and a half broad in the middle: the spikes terminating, single or solitary; sometimes, but very seldom, double; sometimes also from the sides of the branches, reflex only at the end: the flowers sessile, pointing one way, approximating in a double row, small, blue. It is a native of the West Indies, and annual or biennial, flowering in July and August.

There is a variety which is a smaller plant, seldom more than two feet high; the leaves an inch and half long, and about half an inch broad: the spikes of flowers very slender, and not more than two inches long: the flowers small, and of a light blue colour.

The third has an erect stem, pubescent, a foot high: most of the leaves opposite, except those in the middle of the stem, which are alternate, petioled, lucid, and acute: the peduncles opposite to the leaves, or from the divisions of the stem, longer than the leaves, erect, each having two recurved, imbricate spikes of white flowers. It is annual, and a native of the West Indies, flowering in July and August.

The fourth species has an annual root: the stem round, very smooth, with a glaucous bloom on it: the branches trail on the ground, and grow a foot (or sixteen inches) in length: the leaves are somewhat blunt, quite entire, upright, on very short petioles, some alternate, others opposite, whitish, and smooth: the spikes in pairs on a common peduncle, and recurved: the corolla white, with a yellow base, and an open throat. It is a native of the West Indies, flowering in June and July in this climate.

The fifth rises with a woody stalk three or four feet high, dividing into many branches, with leaves upon long foot-stalks; hairy, and of an ash colour on their under side: the flowers are produced from the side of the branches on pretty long peduncles, each sustaining four short roundish spikes or heads, which divide by pairs,

and spread from each other: the flowers are white, and appear in June and July, but are not succeeded by seeds in this climate. The leaves, when bruised, emit an agreeable odour, for which it is by some much esteemed. The gardeners give it the title of Madam Maintenon. It grows naturally in the Canary Islands.

Culture.—The first is raised either by seeds or cuttings. In the first method the seeds may be sown upon a moderate hot-bed, or in pots to be plunged in a hot-bed in the early spring. When the plants have attained some growth, they should be removed into separate small pots filled with light earth, replunging them into the hot-bed, and giving them proper shade till well rooted.

They should afterwards be gradually inured to the open air, so as to be set out in warm situations in the summer. In the autumn and winter they should have the protection of a good green-house.

The cuttings should be planted in pots of light earth in the summer season, plunging them in a mild hot-bed. They soon take root, and afterwards require the same management as the seedlings. They seldom, however, make so good plants.

The three following sorts are increased by sowing the seeds on a hot-bed in the early spring, removing them as the heat declines to another hot-bed when necessary, managing them as Balsams and other tender annuals; and in the middle of the summer, removing them to the situations where they are to flower, with balls of earth about their roots.

The last sort is increased by planting cuttings of the young shoots in the summer in pots, or in a shady border, giving them water pretty freely. When well rooted, they may in the latter case be carefully taken up and put in pots, placing them in shady situations till fresh rooted.

They afterwards require the protection of the green-house from frosts and severe weather, being placed with plants of the more hardy sorts, such as Myrtles, and that require free air in mild weather.

The first and last sorts are very ornamental among potted green-house plants of the more hardy kinds; and the others among the more tender flowery plants in pots and borders.

HELLEBORE. See **HELLEBORUS**.

HELLEBORUS, a genus containing plants of the herbaceous perennial kind.

It belongs to the class and order *Polyandria Polygynia*, and ranks in the natural order of *Multisiliquæ*.

The characters are: that there is no calyx, unless the corolla, which in some species is permanent, be considered as such: the corolla has five

petals, roundish, blunt, large: nectaries several, very short, placed in a ring, one-leaved, tubular, narrower at bottom: mouth two-lipped, upright, emarginate, the inner lip shortest: the stamina consist of numerous subulate filaments: anthers compressed, narrower at bottom, upright: the pistillum consists of about six germs, compressed: styles subulate: stigmas thickish: (five or more:) the pericarpium consists of capsules (leguminous, beaked) compressed, two-keeled: the lower keel shorter; the upper convex, gaping: the seeds several, round, and fixed to the suture.

The species cultivated are: 1. *H. hyemalis*, Winter Hellebore, or Yellow Winter Aconite; 2. *H. niger*, Black Hellebore, or Christmas Rose; 3. *H. viridis*, Green Hellebore; 4. *H. foetidus*, Stinking Hellebore, or Bear's-foot; 5. *H. lividus*, Livid Purple, or Great Three-flowered Black Hellebore.

The first has a tuberosus transverse root, with many dependent fibres, putting up several naked stems or scapes, simple, smooth, round, from an inch or two to four inches in height, terminated by a single leaf, spreading out horizontally in a circle, divided into five parts almost to the base, and the parts simple, or divided into two, three, or four lobes. In the bosom of this sits one large, upright, yellow flower. It is native of Lombardy, and flowers with us from January to March.

The second has transverse roots, externally rough and knotted, with many dependent fibres, and some large roots striking down; the scapes from six inches to near a foot in length, round, upright, variegated with red, rising from a sheath, and terminated usually with one flower, sometimes two, and very rarely three: corolla very large, generally white at first, but frequently with a tint of red, growing deeper with age, but finally becoming green. It is a native of Italy, &c. flowering from December to March. Martyn observes, that "it has the name of *Black Hellebore* from the colour of the root; and of *Christmas Rose*, from the time of flowering and the colour of the corolla."

The third has a round stem, a little branched at top, but not near so much as in the next sort; leafy, reddish at the base, upright, smooth, a foot or eighteen inches in height: the leaves not of a stiff leathery consistence, as in the next species, but soft and of a lighter green; those from the bottom are on long petioles, but those on the stem sit close to their sheaths: the leaflets (seven to ten) lanceolate, acuminate, sharply serrate, smooth, gashed, usually trifid, the divisions sometimes deeply lobed; and at the base of each peduncle is a similar leaf, only smaller: the peduncles axillary, an inch long, round; supporting two (sometimes only one) nodding,

2 *Althaea Frutescens*

green flowers. It is a native of France, &c. flowering in March and April.

The fourth has a small but bent root, with a prodigious number of slender dark-coloured fibres: the stem is from eighteen inches to near a yard in height, towards the bottom round, strong, naked, marked with alternate scars, the vestiges of former leaves; dividing and subdividing at top into many branches, producing great abundance of flowers pendent, of a pale yellowish colour: the leaves composed of eight or nine long narrow lobes, joined at their base, commonly four on each side, united at the bottom, and one in the middle of the foot-stalk, serrate, and ending in acute points; those on the lower part much larger than those on the upper, of a deep green colour. It is a native of Italy, &c. flowering from November or December to April.

The fifth species resembles the third, but differs in having trifoliate leaves, broader and entire, their surface being smoother, and the stalks rise higher than either of the common sorts. It flowers from January to May.

Culture.—The first sort is increased by planting the off-sets from the roots after the leaves are decayed, in the latter end of the summer season, in the places where they are to flower, in patches of several roots together. They have the best effect when intermixed with the Snow-drop, as being of similar growth, and flowering about the same time. The off-sets may be separated from the old plants every three or four years.

The second sort is increased by parting the roots in the autumn, and planting them out in moist warm sheltered situations, in the borders or other parts where the soil is fresh and unmanured. And to have it flower well, it should be protected by glasses in the winter. Some plants may be potted in this intention.

The third and fourth sorts are raised by sowing the seeds in the autumn or early spring, either in the places where they are to grow, or in beds for the purpose, afterwards thinning them out to a few plants, or transplanting them into other beds, at the distance of a foot in the rows.

They rise well from self-sown seed, and succeed in shady situations very well.

The last sort is increased by seeds and parting the roots.

The well ripened seeds should be sown, or the roots planted out, in the autumn, either in pots of light fresh earth, or in warm protected situations in the borders. The plants should afterwards be protected in the green-house, or by hand-glasses in the winter. But they do not increase fast in either of these ways.

These are all ornamental plants; the first sort in the fronts of beds, borders, and clumps; and the third and fourth in the large borders and wilderness parts of pleasure-grounds. The se-

cond and last sorts produce a fine effect among collections of potted plants.

HELMET-FLOWER. See ACONITUM.

HELONIAS, a genus containing plants of the hardy herbaceous flowering perennial kind.

It belongs to the class and order *Hexandria Trigynia*, and ranks in the natural order of *Coronarieæ*.

The characters are: that there is no calyx: the corolla has six petals, oblong, equal, deciduous: the stamina have six subulate filaments, a little longer than the corolla: anthers incumbent: the pistillum is a roundish germ, three-cornered: styles three, short, reflex: stigmas blunt: the pericarpium is a roundish capsule, three-celled: the seeds roundish.

The species are: 1. *H. bullata*, Spear-leaved Helonias; 2. *H. asphodeloides*, Grass-leaved Helonias.

The first has a perennial root, composed of many thick fleshy fibres: the leaves spreading near the ground, and sitting close to the root at their base, of a light green colour, having six longitudinal nerves, which appear strongest on the under side; they are four or five inches long, two or three broad in the middle, narrowing gradually to both ends, and continuing green all the year. In the centre of these springs up a single erect stalk, a foot in height, having a few vestiges of small leaves, ending in sharp points, standing alternately close to the stalk: this is terminated by a close obtuse spike of dark-red flowers, with petals spreading open, flat: the filaments are twice the length of these; and the anthers are four-cornered, of a blue purple colour. It is a native of America, flowering the latter end of June (April and May).

The second species has the stem extremely simple, two feet high: the leaves alternate or scattered, upright, even, but rugged at the edge: the flowers are white, in a simple, terminating raceme, on peduncles longer than the flowers. It is a native of Pennsylvania, &c. flowering in May and June.

Culture.—These plants are increased by planting off-sets taken from the roots in autumn; or by sowing the seeds as soon as they are ripe, in a light fresh soil: they are hardy enough to thrive in the open air; but must not be removed oftener than once in three or four years. They require the same length of time in coming to flower when raised from seed.

These plants afford variety among others of similar growth in the principal flower compartments.

HEMEROCALLIS, a genus containing plants of the herbaceous flowery perennial kinds.

It belongs to the class and order *Hexandria Monogynia*, and ranks in the natural order of *Liliacæ*.

The characters are: that there is no calyx: the corolla is six-parted, bell-funnel-form: tube short: border equal, spreading, more reflex at top: the stamina have six subulate filaments, the length of the corolla, declining; upper ones shorter: anthers oblong, incumbent, rising: the pistillum is a roundish germ, furrowed, superior: style filiform, the length and situation of the stamens: stigma obtusely-three-cornered, rising: the pericarpium is an ovate-three-lobed capsule, three-cornered, three-celled, three-valved: the seeds very many, and roundish.

The species are: 1. *H. flava*, Yellow Day-Lily; 2. *H. fulva*, Copper-coloured Day Lily.

The first has strong fibrous roots, to which hang knobs, or tubers, like those of the Asphodel, from which come out leaves, two feet long, with a rigid midrib, the two sides drawing inward, so as to form a sort of gutter on the upper side: the flower-stalks rise two feet and a half high, having two or three longitudinal furrows; these are naked, and at the top divide into three or four short peduncles, each sustaining one pretty large yellow flower shaped like a Lily, having but one petal, with a short tube, spreading open at the brim, where it is divided into six parts; these have an agreeable scent, from which some have given them the title of Yellow Tuberose. It is a native of Siberia, &c. flowering in June.

There is a variety with smaller roots; the leaves are not near so long, have not more than half the breadth, and are of a dark green colour: the flower-stalk is a foot and half high, naked and compressed, without furrows; at the top are two or three yellow flowers, which are nearer the bell-shape than the others, and stand on shorter peduncles.

The second species is a much larger plant than the first, and the roots spread and increase much more; the roots have very strong fleshy fibres, to which hang large oblong tubers: the leaves are near three feet long; hollowed like those of the former, turning back toward the top: the flower-stalks are as thick as a man's finger, and rise near four feet high; they are naked, without joints, and branching at the top, where are several large copper-coloured flowers, shaped like those of the Red Lily, and as large. These flowers never continue longer than one day, but there is a succession of flowers on the same plants for a fortnight or three weeks. It flowers in July and August.

Culture.—These plants are easily increased by planting the off-sets taken from the roots in autumn in any situation, as they are extremely hardy. They afterwards require no other culture, but to keep them clean from weeds, and to allow them room, that their roots may spread.

The first sort may also be increased by seeds, which should be sown in autumn. The plants

come up in the following spring, and these will flower in two years.

A moist soil and shady situation are the best suited to their growth; their size, and the great increase of their roots, especially in the second sort, render them most proper for large gardens and plantations, where they produce much variety and effect.

HEPATICA. See ANEMONE.

HERB, such a plant as rises with leaves and stalks annually from the root, the stalks not becoming woody or durable.

Many of the kitchen-garden esculents, and a great variety of ornamental or flowery plants, are of this kind. See HERBACEOUS PLANTS.

Many under-shrubby esculent and other plants are also sometimes considered as Herbs; such as sage, thyme, rue, hyssop, winter-savory, lavender, &c.: but these having ligneous, durable stalks and branches, more properly belong to the shrubby tribe.

HERBACEOUS PLANTS, such as have the properties of herbs.

All such as produce leaves and stalks annually from the root, and whose stalks or stems remain green and succulent, or soft, and do not become woody, or durable, but die down to the root every year, soon after they have produced flowers, &c. are properly of this sort, and of which there are annuals, biennials, and perennials.

They are thus very distinguishable from the woody kinds, such as trees, shrubs, and under-shrubs, whose stems and branches are woody or ligneous, and durable.

Of this class are most of the esculents of the kitchen-garden, except those of the under-shrubby kinds, such as sage, thyme, hyssop, &c. vast numbers of the flowery kinds for the pleasure-garden, almost all the annuals and biennials; as also all the perennials, both the fibrous, bulbous, and tuberous-rooted kinds, whose stalks decay annually.

HERMANNIA, a genus containing plants of the shrubby exotic kind.

It belongs to the class and order *Monadelphia Pentandria*, and ranks in the natural order of *Columnifera*.

The characters are: that the calyx is a one-leaved perianthium, five-cleft, roundish, inflated: the little clefts bent in, permanent: the corolla pentapetalous, spiral against the sun: claws the length of the calyx, with a little membrane on each side converging into a cowed nectareous tube: border spreading, broadish, blunt: the stamina have five filaments, broadish, very slightly coalescing at bottom into one body: anthers upright, acuminate, converging: the pistillum is a roundish germ, five-sided, five-cornered: styles five, filiform, approximating, subulate, longer than the stamens: stigma simple: the

pericarpium is a roundish capsule, five-sided, five-celled, gaping at the top: the seeds very many, small, (kidney-form).

The species cultivated are: 1. *H. althæifolia*, Marsh-Mallow-leaved Hermannia; 2. *H. alnifolia*, Alder-leaved Hermannia; 3. *H. hyssopifolia*, Hyssop-leaved Hermannia; 4. *H. lavendulifolia*, Lavender-leaved Hermannia; 5. *H. grossularifolia*, Gooseberry-leaved Hermannia.

The first seldom rises more than two feet and a half high: the stem is not very woody, and the branches are soft and slender. The flowers are produced in loose panicles at the ends of the branches; are larger than those of the alder-leaved sort, and have hairy calyxes: they come out in June and July, and frequently again in the autumn. It is a native of the Cape.

The second species rises with a shrubby stalk six or eight feet high, dividing into many erect irregular branches, covered with a brown bark: the leaves narrow at their base, but broad and round at the top, about an inch long, and three quarters of an inch broad at the top: the flowers are produced in short spikes on the upper part of the branches; are of a pale yellow colour, and small; appearing in April and May.

The third rises with a shrubby upright stalk to the height of seven or eight feet, sending out many woody lateral branches, growing very erect: the leaves are about an inch and half long, and half an inch broad, serrate towards the end: the flowers come out in small bunches from the side of the stalk; are of a pale straw colour, appearing in May and June, and frequently followed by seeds, which ripen about the end of August.

The fourth species has shrubby branching stalks, which are very bushy, but seldom rise more than a foot and half high; the branches are very slender, and have hairy, pale-green leaves of different sizes; some of them two inches long, and an inch broad at their ends, but their common size is seldom more than one inch long, and half an inch broad; they are entire, and sit pretty close to the branches. The flowers come out from the side of the stalk singly, are small and yellow, continuing most part of the summer.

The fifth is a shrub of lower stature than the alder-leaved sort; but sends out a great number of branches, which spread wide on every side; the leaves are smaller than in that, rough and sessile: the flowers are produced in short close spikes at the end of every shoot, so that the whole shrub seems covered with them; they are of a bright yellow, and appear towards the end of April, but are not succeeded by seeds in this climate.

Culture.—These plants are all capable of being increased by planting cuttings of their young shoots in the early spring and summer months, in pots of good rich earth, plunging them in the first case in a moderate hot-bed, and giving them proper shade and water.

When they have stricken good root they should be removed with balls of earth about them into separate pots, filled with good light fresh earth, placing them in a shaded situation till perfectly re-established; when they should be exposed to the open air during the summer, but in the autumn and winter protected in the green-house, being deposited in an airy situation with myrtles and other similar plants.

They may likewise be raised from seed when it is good, here, or procured from abroad, by sowing it in pots of good mould, and plunging them in a hot-bed. The plants should be removed when of proper growth.

They afford ornament and variety among other potted evergreen plants.

HERNANDIA, a genus comprising plants of the evergreen exotic tree kind.

It belongs to the class and order *Monoecia Triandria*, and ranks in the natural order of *Tricoccæ*.

The characters are: that the male flowers are by pairs, lateral in each umbel: the calyx is a partial involucre, four-leaved, three-flowered: leaflets ovate, obtuse, spreading very much: there is no perianthium: the corolla has six petals, subovate, spreading; the three inner ones narrower: nectary, six glands, round-headed, placed round the filaments: the stamina consist of six filaments (three) shorter than the petals, inserted into the receptacle: anthers upright, oblong, large: female flower intermediate: the calyx is an involucre common with the males: perianthium inferior, one-leaved, bell-shaped, entire, permanent (inflated): the corolla has eight petals, of which four are interior and narrower, all sitting on the germ (petals six): the nectary has four glands, obovate, alternate with the interior petals: the pistillum is a roundish germ: style filiform: stigma oblique, somewhat funnel-shaped, large: the pericarpium is a dry drupe, ovate, eight-furrowed, one-celled, inclosed in a very large, inflated, roundish, fleshy, coloured perianthium, with the mouth entire: the seed is a globular nut, which is slightly depressed.

The species cultivated is *H. sonora*, Whistling Hernandia.

It is in its native situation an upright lofty tree, with an elegant head: the flowers are of a pale yellow colour, in paniced racemes; the calyxes of the fruit are yellow. It is common

in the West Indies, and there often termed Jack-in-a-box Tree.

The whistling noise which it produces is ascribed by Brown to the cups that sustain and partly envelop the nuts, which being large, as they move in the wind produce the sound.

Culture.—They are increased by sowing the seeds in a hot-bed in the spring. When the plants are two inches high, they should be transplanted each into a separate pot, filled with fresh rich earth, and plunged into the hot-bed again, observing to water and shade them until they have taken root; after which air should be admitted by raising the glasses, in proportion to the warmth of the atmosphere, and the heat of the bed, watering them frequently. As they advance they should be removed into larger pots, being careful not to break the roots, and to preserve a good ball of earth to them: when their leaves droop they should be screened from the sun until they have taken new root. They should be shifted in July, that they may be well rooted before the cold approaches. They must be kept constantly in the bark-stove; giving them in winter a moderate share of heat, and in summer plenty of air, when the weather is hot.

They produce a fine effect among other stove plants.

HESPERIS, a genus containing plants of the hardy herbaceous flowery kind.

It belongs to the class and order *Tetradynamia Siliquosa*, and ranks in the natural order of *Siliqueae*.

The characters are: that the calyx is a four-leaved perianthium: leaflets lanceolate-linear, from parallel converging, at top incumbent, at bottom gaping, deciduous: of these two opposite ones are gibbous at the base: the corolla is four-petalled, cruciform: petals oblong, the length of the calyx, a little bent back obliquely contrary to the sun's apparent motion, ending in attenuated claws, the length of the calyx: the stamina have six subulate filaments, the length of the tube; two of them shorter by half than the others: anthers linear, upright, reflex at the tip: an acuminate honeyed gland between each shorter stamen and the germ, and surrounding the stamen: the pistillum is a germ the length of the calyx, prismatic, four-cornered: style none: stigma two-parted, placed on the inside, oblong, upright, forked at the base, converging at the tip, withering: the pericarpium is a silique, long, pressed flat, stiff and straight, two celled, two-valved; the valves of the same length with the partition: the seeds very many, ovate, and compressed.

The species cultivated are: 1. *H. tristis*, Night-smelling Rocket, or Dame's Violet; 2. *H.*

matronalis, Garden Rocket, or Queen's Gilliflower; 3. *H. inodora*, Unsavoury Rocket.

The first has the leaves much larger than in those of the Garden Rocket, and of a paler green; the stalks are closely set with bristly hairs: the flowers grow in loose panicles at the top of the stalk, and appear about the same time with those of the second sort. It is a native of Austria, being much cultivated abroad for the great fragrancy of the flowers in the evening. In Germany pots of it are placed in the apartments of the ladies; whence it has the name of Dame's Violet.

The second species rises with an upright stalk a foot and a half high, with spear-shaped leaves which sit close to the stalk, and are slightly indented on their edges, ending in acute points: the flowers are produced in a loose thyrse on the top of the stalks: the petals are roundish and indented at the points, of a deep purple colour, and smell very sweet, especially in the evening or in cloudy weather. It flowers in June, and the seeds ripen the latter end of August. It is a native of Italy.

It varies with single purple flowers, with double flowers of both colours, and with a mixture of both.

The *Siberian* variety differs in having a stalk of twice the height: the corolla is purple, not white, and in the claws of the petals being twice as long as the calyx, and the border blunt, and scarcely, if at all, emarginate.

The third rises with an upright stalk near two feet high: the leaves are dark, green, and sessile: the flowers grow in loose spikes on the top of the stalks; in some they are white, in others purple, and sometimes both colours striped in the same flower. They have no odour. It resembles the second species so much as scarcely to be distinguished from it.

It varies with double flowers in both colours.

Culture.—They are increased either by seeds, offsets from the roots, or by cuttings of the flower-stalk.

The seed should be sown in a bed or border of light earth, and either raked in lightly, or covered a quarter of an inch deep with light mould in the early spring. When the plants are come up three or four inches in height, they should be planted out in beds six inches apart, to remain till autumn or the following spring, when they should be removed where they are to flower.

As most of these seedlings produce single flowers, and many of these go off after they have flowered, it is proper to raise a fresh supply annually.

The double sorts are propagated with certainty

only by dividing the roots, or by planting cuttings.

In the first method, in order to promote offsets from the root, some good plants should be allotted in any open bed or border for propagation, not suffering them to run up fully to flower; but when their flower-stalks have advanced about eight or ten inches high, to cut them down close to the ground; and as they shoot again, to cut them also off; as, by thus stopping their upright growth, the roots will more readily throw out young offsets from their sides, which will be well formed by the beginning of autumn, when the whole root should be taken up, and the offsets divided separately, and planted in a nursery-bed six inches distant, to remain till the beginning of autumn, or spring following; then removed with balls of earth about their roots to where they are to stand and flower.

The flower-stalks which are thus occasionally cut down to promote the increase of offsets at bottom, may be divided into lengths, and planted as directed below; each cutting will form a plant for flowering the following year.

This practice should be pursued annually to keep up the stock of double flowers; for those which shoot up to full growth and bloom rarely put out any offsets, unless the stalks are cut down as soon as the flowers begin to fade, when sometimes they emit a few, but which are not so numerous or so strong as in the manner directed above.

The cuttings of the flower-stalks may be planted any time in the early part of summer, when the stalks are advanced about a foot in growth, or before they flower, each being cut and divided into two or three cuttings, four, five, or six inches in length. The lower half generally forms the best cuttings. They should be planted in a shady border, putting them two parts into the ground, about three inches asunder, giving water at the time, and repeating it frequently. Many of the cuttings will be well rooted, and form shoots at top in six or eight weeks. To promote their rooting more effectually, they should be covered close with hand or bell glasses, as soon as planted, raising the glasses when they begin to shoot at top, to admit air, to which they should be hardened gradually.

All the sorts are ornamental for the open borders of pleasure-grounds, and to intersperse, in assemblage with other herbaceous plants, towards the fronts of the more conspicuous shrubby clumps, on sides of lawns and walks, being always planted out in autumn, or early in spring, before they advance much for flowering.

HIBISCUS, a genus furnishing plants of the shrubby and flowery exotic kinds.

It belongs to the class and order *Monadelphia Polyandria*, and ranks in the natural order of *Columniferae*.

The characters are: that the calyx is a double perianthium: outer many-leaved, permanent: leaflets linear: more rarely one-leaved, many-cleft: inner one-leaved, cup-shaped, half-five-cleft, permanent: or five-toothed, deciduous: the corolla has five petals, roundish-oblong, narrower at the base, spreading, fastened at bottom to the tube of the stamens: the stamina have very many filaments, united at bottom into a tube, at top (in the apex and surface of this) divided and loose: anthers kidney-form: the pistillum is a roundish germ: style filiform, longer than the stamens, five-cleft at top: stigmas headed: the pericarpium is a five-celled capsule, five-valved: partitions contrary, doubled: the seeds solitary or several, ovate-kidney-form.

The species cultivated are: 1. *H. Syriacus*, Syrian Shrubby Hibiscus, or *Althæa Frutex*; 2. *H. Trionum*, Bladder Hibiscus, Bladder Ketmia, or Flower of an Hour; 3. *H. Rosa Sinensis*, China Rose Hibiscus; 4. *H. mutabilis*, Changeable Rose Hibiscus, or Martinico Rose.

The first rises with a shrubby stalk to the height of six or seven feet, sending out many woody branches, covered with a smooth gray bark: the leaves have the upper part frequently divided into three lobes, placed alternately on the branches, and stand on short foot-stalks: the flowers come out from the wings of the stalk at every joint of the same year's shoot; they are large, and shaped like those of the mallow, having five large roundish petals, which join at their base, spreading open at the top in the shape of an open bell: these appear in August, and if the season is not too warm, there is a succession of flowers part of September. The early flowers are succeeded by short capsules; but unless the season proves warm, they do not ripen in this climate. It is usually termed *Althæa frutex* by the nursery gardeners. It is a native of Syria.

There are varieties with pale purple flowers, with dark bottoms; with bright purple flowers, with black bottoms; with white flowers, with purple bottoms; with variegated flowers, with dark bottoms, called *Painted Lady Althæa frutex*; with pale yellow flowers, with dark bottoms; with variegated leaves, and with double flowers.

The second species rises with a branching stalk a foot and a half high, having many short spines which are soft: usually the leaves are divided into three lobes, which are deeply jagged

almost to the midrib; these jags are opposite, and the segments are obtuse; the flowers come out at the joints of the stalks upon pretty long peduncles; the outer calyx is composed of ten long narrow leaves, which join at their base; the inner is of one thin leaf, swollen like a bladder, cut into five acute segments at the top, having several longitudinal purple ribs, and is hairy; both these are permanent, and inclose the capsule after the flower is past: the flower is composed of five obtuse petals, which spread open at the top, and form an open bell-shaped flower; these have dark purple bottoms, but are of a pale sulphur colour above, tinged sometimes partially with pale purple on the outside, where they are also ribbed: the capsule is ovate, the consistence of paper, pustuled with protuberances occasioned by the seeds, villose and black. It is annual, growing naturally in Italy, &c. The flowers are of short duration, in hot weather continuing only a few hours open; but there is a succession of them daily for a considerable time, in June, July, and August. It has been long known by the title of Venice Mallow.

There are varieties with erect purplish stems, and the flowers larger, and their colour deeper; and with large paler-coloured flowers.

The third, in its native situation, grows to the size of an ordinary tree; but here it is shrubby, the stem round, erect, with alternate, spreading branches, that are wand-like, leafy, brownish-green, and nearly smooth: the leaves alternate, spreading, unequally and coarsely serrate, entire at the base, five-nerved, bright green, very smooth, except the young ones, which are slightly downy; their petioles are round, downy on the upper side: the stipules in pairs, opposite, at the base of the petioles, linear, acute, deciduous: the flowers axillary, solitary, peduncled, large, of a deep scarlet colour, resembling a double rose. It is common in China and the East Indies. It is rare with single flowers.

The fourth species has a pale stem, single, smooth, spreading out wide into leafy branches at top; the wood resembling that of the fig: the leaves are the same size with those of the vine, having the roughness of fig leaves, and the form of both, or rather of the angular leaves of ivy; whitish underneath: the petioles rough, thick, three or four inches in length: the peduncles thicker towards the top, sometimes tinged with red, sustaining large handsome flowers, which alter in their colour, as at their first opening they are white, then they change to a blush rose-colour, and as they decay they turn to a purple. Martyn remarks, that in the West

Indies all their alterations happen the same day; but that in England, where the flowers last near a week in beauty, the changes are not so sudden. It is a native of the East Indies, &c. The period of its blowing in the stoves of this climate is November and December.

It varies with double flowers, from which the single is frequently produced; but the seeds of the single seldom vary to the double kind.

Culture.—The first sort is increased by seeds, layers, and cuttings.

The seeds should be procured from abroad, and sown in pots filled with light earth in the early spring months, plunging them in a gentle hot-bed to bring them forward, or on a border in a warm exposure. They should be watered during the summer, and be protected from frost in the winter. When they have had two years' growth, they may be set out in nursery rows, or be planted where they are to remain.

The layers should be laid down in the autumn, the shoots being cut on the backs at one or two joints, and well laid into the ground. They are generally well rooted in twelve months, when they may be taken off and removed to where they are to remain.

The cuttings of the young shoots should be planted in pots of light earth in the early spring, plunging them in a mild hot-bed; or they may be planted in a shady border in the summer season. When well rooted, they should be carefully taken up and planted where they are to remain, either in the autumn or spring.

The second sort is increased by sowing the seed either in the autumn or spring, in the places where the plants are to flower, in patches of several seeds together. When they come up, they should be thinned out to two or three plants in each patch.

The two last sorts may be increased by sowing the seeds in the early spring months, in pots filled with rich light mould, plunging them in a moderate hot-bed under glasses, or, what is better, in the bark-bed of the stove. When the plants are up, and have attained two or three inches in growth, they should be removed into separate small pots, watering them well, and replanting them in the hot-bed, where they must be kept.

They may likewise sometimes be raised by planting cuttings of the young shoots in pots of the same sort of earth, in the spring or summer, giving them water, and plunging them in the bark hot-bed. They should afterwards be managed as the others.

The two first hardy sorts are highly ornamental in the borders and clumps, among other flowery plants; and the two last tender sorts

produce much variety by their beautiful flowers in the stove and conservatory collections.

HIERACIUM, a genus containing plants of the hardy, herbaceous, flowery, perennial kind.

It belongs to the class and order *Syngenesia Polygamia Æqualis*, and ranks in the natural order of *Compositæ Semiflosculosæ*.

The characters are: that the calyx is common, imbricate, ovate: scales several, linear, very unequal, longitudinal and incumbent: the corolla compound, imbricate, uniform: corollules hermaphrodite, numerous, equal: proper monopetalous, ligulate, linear, truncate, five-toothed: the stamens have five capillary filaments, very short: anther cylindric, tubulous: the pistillum is a subovate germ: style filiform, the length of the stamens: stigmas two, bowed back: there is no pericarpium: calyx converging, ovate: the seeds solitary, obtusely four-cornered, short: down capillary, sessile: the receptacle naked.

The species cultivated are: *H. aurantiacum*, Orange-flowered Hawkweed; 2. *H. chondrilloides*, Gum-Succory Hawkweed.

There are several other species that have been cultivated, but which possess little merit.

The first has perennial, creeping roots: the stem scarcely branched (except with the peduncles), bearded with white hairs placed on black glands, upright, a foot or a foot and a half in height (two feet high): the leaves next the root rather ovate, on the stem ovate-lanceolate or lanceolate, quite entire, dusky green, narrowing into the petiole, obtuse, alternate, the upper ones sessile; the lower ones a span long, and an inch broad: the stipules very small, lanceolate: the flowers eight or ten, orange-coloured, on short pedicels, forming a short panicle. It is a native of Austria, &c. flowering from June to autumn. It was formerly distinguished by the titles *Golden Mouse-ear*; and when of a dark colour, *Grim the Collier*.

It varies in the colour of the flower, from red to orange, and several shades of yellow.

The second species has the stem a span high, and even: the root-leaves petioled, smooth: stem-leaves five or six, alternate, long, with long recurved teeth: the peduncles from the upper axils of the leaves, the same height with the stem, solitary, almost naked, one-flowered. It is a native of the South of France, flowering in June and July.

Culture.—These plants are increased by sowing the seeds in the early spring, on a bed or border of fresh earth, in an eastern exposure. When the plants are a few inches high, they should be removed into other beds, to stand till the autumn, when they should be planted where they are to remain. But it is a better prac-

tice to plant them at first where they are to grow.

They may likewise be increased by planting slips of the roots in the autumn or spring where they are to remain.

In both modes they should be well watered when the season is dry.

The roots continue many years when planted in a soil that is not too rich or moist.

They afford variety in the fronts of the borders, clumps, and other parts of pleasure-grounds.

HIPPOPHAE, a genus furnishing plants of the hardy deciduous shrubby kind.

It belongs to the class and order *Dioecia Tetrandria*, and ranks in the natural order of *Cuculifloræ*.

The characters are: that in the male the calyx is a one-leaved perianthium, two-parted, two-valved, with the bottom entire; the parts roundish, blunt, concave, upright, converging at the tips, and gaping on the sides: there is no corolla: the stamens have four filaments, very short: anthers oblong, angular, almost the length of the calyx. Female—the calyx is a one-leaved perianthium, ovate-oblong, tubular, club-shaped, with the mouth cloven, deciduous: there is no corolla: the pistillum is a roundish, small germ: style simple, very short: stigma thickish, oblong, upright, twice as long as the calyx: the pericarpium is a superior berry, sub-globular, one-celled: the seed single, oblong, hard, shining.

The species are: 1. *H. rhamnoides*, Common Sea Buckthorn, or Sallow Thorn; 2. *H. Canadensis*, Canadian Sea Buckthorn.

The first rises with shrubby stalks eight or ten feet high, sending out many irregular branches, which have a brown bark silvered over: the leaves are narrow or linear-lanceolate, about two inches long, and a quarter of an inch broad in the middle, of a dark green on their upper side, but hoary on their under, with a prominent midrib; the borders are reflexed as in the rosemary; they are placed alternate on every side of the branches, and sit close to them; and there are little, clustered, peltate, ciliate, pale scales scattered over them: the branches spread wide, are straight, stiff, and thorny at the ends; the lesser ones numerous, scattered, short, and spreading: the flowers solitary, appearing before the leaves, generally abortive, unless the shrub grows in its natural situation: the male flowers below the leaves, between a branch and a one-valved, permanent bud, the length of the flower: the female flowers sessile in the axils of the lower leaves: the former are sub-sessile, somewhat spiked, disposed in four rows along the

lesser branches. The flowers come out from the branchlets of the former year; and the berries are abundant, on short peduncles, gratefully acid to the taste. It is a native of many parts of Europe, flowering from May to June. In sunny, sandy situations, it is planted for hedges; and it is used for dyeing yellow.

It varies with red berries.

The second species has the appearance of the first, but the leaves are broader, only half the length, of an ovate or oblong-ovate form; on the upper surface green, with diverging hairs, in bundles, scarcely to be discerned by the naked eye; on the lower, silvery with hairs and scales, and have rust-coloured dots scattered over them; the branches are opposite; and the racemes simple among the first leaves, upright, and shorter by half than the leaves. It is a native of Canada.

Culture.—These shrubs are easily propagated by planting suckers taken off from the roots in autumn, in the nursery. After they have had one year's growth, they are fit to plant out where they are to remain. They may also be increased by layers; but the roots spread and put up such abundance of suckers, that there is no necessity to be at this trouble.

They are also sometimes raised by planting cuttings of the young shoots as above.

As these shrubs have but little beauty, it will be sufficient to have one or two of them in plantations or borders.

HOE, an useful and well-known garden implement.

Hoes are of different kinds, as *Drawing* and *Scuffling Hoes*, and each sort has different sizes.

The first sort is fixed with its edge inward; the workman, in using it, draws it towards him. It is one of the most useful implements of gardening, for many purposes, both for general hoeing, and in drawing drills for sowing many sorts of seeds, loosening the earth about, and moulding up the stems of plants; and hoeing down weeds between all sorts of plants that stand distant enough to admit it. It is the best adapted of any for thinning out esculent crops to proper distances, to acquire their proper growth, such as onions, carrots, parsnips, turnips, spinach, &c.

Of this kind there should be three or four different sizes, from six inches width down to two inches.

The first size is a large Hoe for common use, about six inches long in the plate, by three or four broad, fixed on a long handle for both hands, and is the proper sort to use for all common hoeing work, and for drawing drills, for sowing peas, beans, kidney-beans, &c. with. It

is the most eligible sized Hoe of any for broad-hoeing between rows of all those kinds of plants, and all others that stand distant enough, either in rows or otherwise, for the Hoe to pass between them, both to cut down weeds and loosen the ground, and to earth up the stems of the plants, and for all other purposes of hoeing where the plants stand distant, both in the kitchen- and pleasure-garden.

The second size should be about four inches in the plate long-ways, and the same breadth as the above. It is useful for drawing drills, and for hoeing among various plants, where the former sort of Hoe cannot be commodiously employed; as well as to thin some sorts of esculent crops that require moderate distances; such as Dutch turnips, general crops of carrots, parsnips, &c. It is also a proper sized Hoe for hoeing common flower-beds and borders, &c. with.

The third size should be two inches and a half, or not more than three inches broad in the plate; and be fixed on a short handle to use with one hand in small-hoeing, thinning out several sorts of esculent crops, and other work among close-growing plants. A similar one should also be had fixed on a longer handle, to use two-handed in hoeing borders and other compartments of smaller plants, standing near together both in the kitchen-ground and flower-garden, &c. This sized hoe, on a short one-hand handle, is likewise particularly useful for small-hoeing, moulding, and thinning out many kitchen-garden crops in young growth; such as onions, leeks, carrots, parsnips, spinach, &c. to cut them out to the proper distances. It is also a very convenient size for use on many other occasions of hoeing; and for drawing small drills for sowing many kinds of seeds; and hoeing up flower-beds, &c. where the larger Hoes cannot be readily admitted between the plants, so as to stir the mould effectually.

The fourth size should be about two inches width, and fixed in a short handle. It is proper for small-hoeing onions and small crops of carrots, radishes, &c. the first time, where they stand pretty close, and where it is not designed to thin them out at once to their full distance, but to leave them rather thickish for culling, &c.

The edges of the Hoes should constantly be kept sharp by occasional grinding, that they may cut clean.

The second sort, or Scuffling Hoe, is commonly called a *Dutch Hoe*. It is fixed with the edge outward on the end of a long handle, so as that the person using it may push it from him, going backward, and never treading on the hoed

ground, as with the drawing hoe. In regard to size, it should be from about four to six or eight inches wide, open in the middle, for the mould and weeds to pass through, so as not to be drawn in heaps; having a long socket at the back part, in which to fix the handle, which may be five or six feet in length.

It is very proper for scuffling over any piece of ground to destroy weeds, that is clear from crops, or between crops that stand wide, with which a person may make considerably more expeditious work than with a drawing hoe, especially when the weeds are not suffered to grow large; in which case one man can often do as much as two with the other sort. It is not proper for hoeing out crops of esculent plants, or for earthing up the stems of plants, nor for hoeing where the plants stand close. But it is very useful for cutting down weeds in shrubberies and wilderness quarters, where the shrubs stand distant from one another. And it is the best sort of any for scuffling over sand-walks, or others made of loose materials, in order to destroy weeds, moss, &c.

In a small size it is also found useful to run over flower borders, to cut up straggling weeds; as, being fixed on a long handle, the work may be effected by standing in the walks, without treading on the borders or beds.

A sort of triangular Hoe has also been lately found very useful in hoeing many sorts of small crops.

HOEING, a necessary operation performed by the hoe, to destroy weeds, loosen the soil, and mould up the stalks or stems of plants.

It is an expeditious method of destroying weeds between all sorts of plants that stand distant enough to admit it.

When principally designed to destroy weeds, it should always be performed to some depth, and in dry weather, the more sunny the better, especially when the weeds are not to be raked off, that they may die as they are cut down, or at least be so much flagged or withered by the sun and air as not to grow again.

This sort of work, besides destroying weeds, is likewise useful in loosening the surface, and disposing the ground to receive the greater benefit from the air, dews, rains, &c. to the great nourishment of all sorts of plants, and, by breaking up the surface, dividing the clods, and stirring the earth, keeping it fresh, and proving a very beneficial culture to all vegetables. In soils apt to bind after much wet, which causes the plants to appear of a stunted growth, hoeing is of vast advantage in promoting their growth.

The application of earth about the stems of plants, such as earthing up rows of peas, beans, kidney-beans, cabbages, cauliflowers, &c. is

constantly of great service in promoting the strength and vigour of the crops, as well as in giving them a neat appearance.

It is also beneficial in thinning out many close-standing crops to proper distances, cutting out the superabundant plants and weeds, and loosening the soil.

HORSE-DUNG, that which is produced in the stable.

It is a material of great utility in garden culture, for the purpose of forming hot-beds for various early productions and tender plants, and afterwards as manure. See **DUNG** and **MANURE**.

This sort of manure is mostly of a littersy nature, from the great quantity of straw that is mixed and blended with the dung and urine of the horses. On this account it is more disposed to the production of heat, or the taking on the process of fermentation, than other sorts, and is of course better suited to the purpose of forming hot-beds with than any other.

For this use, it should be such as has remained together in the common dung-hill or heap till collected in proper quantity; and if it have commenced some fermentation, or become wholly, or in part, of a moist, warm, steamy quality, it is preferable. If, on turning it up with the dung-fork, it begins to assume a blackish appearance, not rotten, or exhausted and dry, but abounding in a fresh material substance, of a lively, moist, steamy warmth, it is in a good state for this purpose. Fresher dung

fall of moist, warm, steamy litter, is also very desirable, as it may be readily brought to a proper condition.

In this sort, it is the best method to throw it up, to gather and mix the different parts well before it is made use of in preparing the beds.

But for the purpose of manure it is more proper for most sorts of crops when it is more reduced, and brought into a soft, moist state.

HOT-BED, a sort of bed constructed for the purpose of producing artificial heat.

These beds are mostly formed either of horse-dung or tanner's bark, being raised two, three, or four feet high, and covered with garden-frames and glasses, &c.

It is by the aid of these beds that various tender plants, flowers, and fruits, are raised in perfection, which, without such artificial heat, could not possibly be produced or continued in this climate. By this means, likewise, vast numbers of seeds, which would otherwise remain years in the earth, and some never grow at all, are made to germinate, form plants, continue their growth, and produce their flowers and fruits, as in their native soils. And the cuttings and slips of many sorts of trees and shrubs, which would otherwise remain inactive and perish, are also made soon to emit root, fibres, and shoots, and become plants.

By this means, likewise, many valuable esculent plants that succeed in the full ground at one time of the year or other, are brought to perfection much sooner than they could otherwise be obtained, as the cucumber, asparagus, peas, beans, kidney-beans, radishes, carrots, strawberries, and various salad herbs, and other plants, which grow in the open ground.

Annual flowering plants, as well as those of the herbaceous and shrubby kinds, are also brought to more early perfection and flowering by them. They are therefore of great use in the practice of gardening.

Dung Hot-beds.—The proper situations for making these beds in are the forcing-ground, or other sheltered, warm, sunny exposures.

Hot-beds are sometimes made entirely on level ground, and sometimes in a trench or oblong cavity formed in the ground, the width and length of the intended bed, and from twelve inches to a foot and half deep or more; but for early work in winter or spring, they should be mostly above ground, upon the level rather elevated surface, that the bottom of the bed may stand dry, and not be liable to be chilled by wet, as, when made in this way in those seasons, when the heat declines, both sides of the bed may be lined with hot dung quite to the bot-

tom, so as the whole bed may have an equal benefit of the lining to revive its declining heat, which is essentially necessary during winter and spring, until the middle or latter end of May. But when Hot-beds are made in trenches at an early season, when linings must be added to support a constant regular heat, all that part of the beds within the ground is deprived of the advantage of them.

The forms and dimensions of dung Hot-beds should generally be that of long squares, ranging nearly east and west, to any length convenient; about four feet and a half broad, if to be covered with common garden-frames; and three and a half or four feet, if for hand-glasses; raising them, if in winter, or early in spring, three or four feet or more high, allowing for settling, as they will settle half a foot or more in a week or two's time after making. The early beds should be substantial, otherwise they will not support a durable uniform temperature of heat for continuing the plants in a regular, free growth; which, by aid of linings, must be effected till the arrival of warm weather. Those made in winter should be three feet and a half high, at least, when first made; or if four, the better; in March a yard high, in April the same, or two feet and a half, and in May two feet.

They may be made for a one-light, two-light, or three-light frames, and for two, three, or more three-light frames in a range, according to circumstances.

Forming the Beds.—After marking them out, some of the longest or most strawy dung should be shaken along the bottom, to begin the bed with; then the long and short together, as it comes to hand, shaking it evenly on every part, raising the sides perfectly upright, straight, and as firm as possible; forming the corners also full and very firm, keeping the middle well filled with the best dung; and, as the work advances, beating each layer of dung evenly and firmly down, with the dung-fork; or, when it is very long, loose, strawy dung, treading it in to settle every part equally; proceeding in this manner till the bed is arrived to its designed height, raising that intended for frames, two or three inches higher in the back or north side than in front, to give the greater slope to the glasses to the sun, finishing the top even in every part; and when the bed is thus raised, trimming up all the short dung remaining at last round the bed, laying it on the top ridgeways along the middle, which may either then, or rather, if a strong bed, in a few days after, when the bed has settled a little, be levelled, to make good all inequalities, and smooth the surface. After this, set the frame, &c. on, and earth the bed as

directed below. See FRAMES and HAND-GLASSES.

The Hot-bed being thus formed, when of considerable substance, it may be advisable to defer the framing and earthing it finally for several days, or a week or more, according to the strength of the bed, until a little settled, and the first violent heat has subsided; as the heat will be very strong, and frequently of a burning nature for the first week or two after it is made. It may, however, often be proper to set the frames and glasses on, to defend the bed from excessive rains or snow, as well as to draw up the heat sooner, to forward the bed to a proper temperature for the reception of the mould, and seeds or plants. The upper ends of the lights should be raised a hand's breadth high, or shoven so much down in dry weather, that the great steam arising may pass freely off; as in strong Hot-beds neither the earth, seed, or plants, should be put in till the fierce heat and violent steam have a little abated. Hot-beds of slender substance may, however, be framed, earthed, &c. as soon as made, as no great danger is to be apprehended from burning, and more particularly those for small frames, hand-glasses, &c.

Where there is an extensive range of substantial Hot-beds, the placing the frames on them before they are fixed for good, is often inconvenient; in which case it is proper to have mats, or dry long litter, ready to cover the tops in case of excessive rains or snow, which might chill and retard the beds greatly from becoming of a due temperature for the reception of the earth, &c. and sometimes occasion them to become of a burning quality, when they otherwise would be of a regular heat.

In Hot-beds designed for strength and duration it will, as soon as they are made, be proper to provide some sharp-pointed sticks, two feet long, to thrust down into the middle of the beds in different parts, that by pulling them out daily, and feeling their lower parts, a judgment may be formed of the working and temperature of the beds, and when in a proper state for the reception of the mould and plants.

When the Hot-bed is therefore of good substance, and for the large frames, it is proper to let it remain some days to settle, before it is framed for good, because, notwithstanding all the care in making, it will often settle unequally, and should be levelled before it is earthed; in from about three to five, six, or eight days, according to the nature of the dung, or substance of the bed, it will have so far settled as to discover the inequalities, if any; when, if the frames and glasses were placed thereon for the purposes

above mentioned, when the whole has settled, all the inequalities should be made even by levelling the top, making the surface firm, and smoothing it off neatly with the back of the spade. Then the frame and glasses should be put on for good, opening the lights a little at top to give vent to the steam.

Earthing the Beds.—As substantial dung Hot-beds, after being covered with the frames, &c. sometimes heat violently the first week or fortnight, when the earth is put in during the fierce heat, by confining the heat and steam still more closely, it is in danger of being burnt, and also of destroying the seed and roots of the plants, if any were sown or planted. When the earth is thus burnt by the heat of the dung, no seeds or plants can vegetate or thrive in it; it must therefore be taken out, and be replaced by fresh compost. Hot-beds of considerable substance should of course be examined previous to moulding them, to ascertain the state of heat daily, both by the sticks, and thrusting the hand down into the dung. And when it is found of a due temperature, the mould should be put on. This is sometimes shown to be the case by the appearance of a sort of mushroom spawn.

But in slender Hot-beds, as their heat is never so violent or durable, they may either be earthed as soon as made, or in two, three, or four days afterwards, as judged proper. In all cases care should however be taken that the beds do not lose any time, for them to waste their heat ineffectually, without being earthed.

For all sorts of Hot-beds the earth or mould should be rich, light, and of a dry quality, particularly for early work in winter and spring, and tender plants, such as cucumbers, melons, tender annuals, &c. as very moist earth rots such plants while young, binds too close, and by its compactness confines the heat and steam, so as often to burn at bottom, and scorch the roots of the plants. Some light mould should therefore be always in readiness in some airy shed, for two or three weeks before it is wanted. See COMPOST.

The depth of earth or mould necessary to be applied over Hot-beds, must be different according to the purposes for which they are designed, as for sowing seed on, or the reception of plants, and the nature of the plants, or chiefly for plunging pots in. In general, however, from about five or six, to ten or twelve inches, is the common depth. For sowing seeds to raise plants for transplantation, the depth of mould should be about six inches; and where they are to remain to acquire their full growth, not less than from six or eight to

ten or twelve inches in depth. If for the immediate reception of plants, to remain, or for striking cuttings of any sort in, &c. from six to eight, ten, or more inches of mould will be necessary; regulating the whole in some proportion to the nature or growth of the plants, and the substance of the beds. Thus, cucumbers and melons, which are not only extensive growers, but produce large fruit that requires much nourishment, need a greater depth of mould than small salad-herbs, &c.

In earthing the beds, every part of the dung within the frame should be carefully covered over, especially after the plants are come up, or any planted, that no steam may rise immediately from the dung upon them.

In regard to sowing or planting seeds or plants in Hot-beds of strong substance, under frames, care should be taken not to do it till the danger of burning is over, unless performed in pots, that may be moved up as occasion requires; and at any rate it is always better to wait a day or two, than to endanger burning the plants; time should not however be lost when the bed is ready, as it is necessary always to have a lively heat at first, to promote a quick germination in the seeds, or to strike and set the plants forward so as to assume a free growth at first.

In the management of Hot-beds after being sown or planted, it must often be different, according as the different plants may require. In general, however, after the seeds or plants have been put in, the glasses are to be continued constantly on until the middle of summer, when the weather is become settled and warm, particularly for all the tender kinds of plants; fresh air being admitted daily, at all opportunities, in mild weather, by raising the upper ends of the lights; or, if hand-glasses, by propping up one side, from about half an inch to two or three inches high, according to the heat and steam in the bed, and temperature of the outward air, shutting all close in due time towards evening, and keeping them close every night during the cold weather, covering the glasses every night with mats until June, especially for the more tender sorts of plants.

When the heat of the beds naturally declines or becomes of a weakly temperature, it must be renewed by adding fresh hot dung around the sides, which is called lining the bed, and is particularly necessary for all dung hot-beds, made any time in winter or spring. See LINING.

Sometimes a repetition of new linings is required three or four times, especially for those made in winter, to continue them in a uniform heat; these linings should be made of the hottest dung, and be applied quite from the bottom to

the top of the bed, and about fifteen or eighteen inches wide at bottom, drawing them into about a foot wide at top, raising them four or five inches up the frame, to allow for settling, but not more; for the top of the linings, when settled, should be but very little above the bottom of the frame, lest their heat burn the earth adjoining to the frame within: and to prevent steam from rising too copiously from the linings, a stratum of earth should be laid on the top, two inches thick, continuing it close up to the bottom of the frame, that no steam may rise that way; for the rank steam immediately from dung, without first passing through a body of earth, is destructive to most plants. As the lining settles down lower than the top of the bed, more fresh dung should be added.

Bark Hot-beds.—These are Hot-beds formed of bark or tan, after having been used in tan-vats or -pits, which produces a regular, moderate, and durable heat. See BARK.

Hot-beds of this kind always require to be made in proper bark-pits formed for the purpose of brick-work, or post and planking, to confine the tan in its proper situation. See BARK-PIT.

Where there are proper conveniences of pits, in which to make the hot-beds furnished with frames and glasses suitable, they are superior in many cases to dung Hot-beds, both in raising many early esculent productions, and various curious flowers to early bloom, as well as in the propagation and raising many sorts of tender exotics, from seeds, layers, cuttings, &c. In bark Hot-beds early strawberries and melons may be raised, which, by the regular, moderate, and durable heat which they produce, are generally obtained in great perfection at an early season; likewise, small early crops of dwarf-peas and kidney-beans, &c. and of flowering plants, many sorts may be forced in great perfection of early bloom, both of the bulbous, tuberous, and fibrous-rooted kinds, such as hyacinths, dwarf tulip, jonquils, narcissuses, anemones, ranunculuses, pinks, and many other moderate-growing kinds; also roses, and some other small ornamental flowering shrubs.

Bark Hot-beds are also of great utility in hot-houses, stoves, and forcing-houses, as the principal and most proper and effectual kind of beds for these different departments. See BARK-BEDS.

Forced Crops.—The sorts of crops usually raised in these hot-beds are cucumbers, melons, asparagus, strawberries, kidney-beans, peas, dwarf-beans, radishes, small-salad herbs, and lettuces. And various sorts of seed plants are raised and preserved in this way, such as cauliflowers, early cabbages, red cabbages, early celery, plants

for pricking out, carrots, small white turnip-radishes, Dutch turnips, mint, tarragon, tansey, basil, capsicums, love-apples, coriander, purslane, early dwarf potatoes, and mushrooms, in a bed of a peculiar sort. But those for which these beds are absolutely necessary are all the first sort, and basil, capsicum, love-apple, and mushrooms.

HOT-HOUSE, a sort of garden-erection, mostly formed of glass-work, in which a constant, regular degree of artificial heat by fire and bark hot-beds is kept up.

It is made use of for procuring some sorts of fine fruits, such as the pine-apple, and for raising and preserving various sorts of tender exotics from the hot parts of the world.

In the construction of these houses, a wall of eight or ten feet high or more, is raised behind, with a low wall in front and both ends, on which is placed upright glass-work, four, five, or six feet, and a sloping glass roof, extending from the top of the front to the back wall. Internal flues for fire-heat, in winter, are also contrived, and a capacious oblong or square pit in the bottom space, in which to have a constant bark-bed to furnish a continual regular heat at all seasons; so as in the whole to warm the inclosed internal air always to a certain proper high degree.

Besides the above, these Houses are of great utility in forwarding many sorts of choice or desirable hardy plants, flowers, and fruits, to early perfection, which being sown or planted in pots, and placed in them in winter, or early in spring, the constant heat thus produced forwards them to maturity two or three months or more before their natural season in the full ground; such as kidney-beans, strawberries, &c.: also many sorts of flowering plants, both annuals and perennials, of moderate growth, are forwarded to early bloom; and vines planted in the outside, close to the front, the stem of each introduced through a small hole above, and the internal branches trained up under the glasses, produce grapes at an early period, as in May. In Hot-houses, likewise, early cucumbers may be raised in good perfection; and the seeds, cuttings, slips, &c. of many curious tender plants forwarded exceedingly in their growth, by plunging the pots containing them in the bark-bed. See **STOVE**.

These Houses are mostly ranged lengthways nearly east and west, that the glasses of the front and roof may have the full influence of the sun. This is the most convenient situation for common Hot-houses, either for pines or other exotics.

Some Houses of this sort, instead of being placed in this direction, have lately been rang-

ed directly south and north, having a sloped roof to each side like the roof of a house; also to the front or south end; both sides and the south end front being of glass. These Houses are made from ten or twelve to fifteen or twenty feet wide, the length at pleasure; and from ten to twelve feet high in the middle, both sides fully head height; being formed by a brick wall all round, raised only two or three feet on both sides, and south end; but at the north end like the gable of a house. Upon the top of the side and south end walling is erected the framing for the glass-work, which is sometimes formed two or three feet upright, immediately on the top of the wall, having the sloped glass-work above; and sometimes wholly of a continued slope on both sides, immediately from the top of the side walls to that of the middle ridge. They are furnished either with one or two bark-pits; but if of any considerable width, generally with two ranging parallel, one under each slope of the top glass, separated by a two-feet path running along the middle of the House, and sometimes continued all round each pit, with flues ranged along against the inside walls; the whole terminating in an upright funnel or chimney at the north end.

Other Hot-houses are formed entirely square, having a ten- or twelve-foot brick wall behind; that of the front and both sides, only two or three feet high for the support of the glass-work, placed upright nearly the same height, and sloped above on both sides and front, which are wholly of glass. These are furnished within with bark-pits and flues, as in the others.

In particular cases they are likewise made semicircular, or entirely circular, being formed with a two or three feet brick wall supporting the glass framing, which is continued quite round; having the bark-pit also circular, and flues carried all round the inside of the walling, terminating in a chimney on the northern side.

The first forms are probably the best for general purposes.

Hot-houses on these plans are made of different dimensions, according to the sizes of the plants they are designed to contain; but for common purposes they should be only of a moderate height, not exceeding ten or twelve to fourteen feet behind, and five or six in front: some are, however, built much more lofty behind, to admit of the taller growing exotics placed towards the back part, to grow up accordingly in a lofty stature; but the above are best adapted to the culture of pines, and other moderate growing plants, as well as for forcing in; as very lofty houses require a greater force of heat, and by

the glasses being so high, the plants receive less benefit from the sun, and are apt to draw up too fast into long slender leaves and stems, as they naturally tend towards the glasses. Where the top glasses are of a moderate distance from the plants, they receive the benefit of the sun's heat more fully, which is essential in winter, and become more stocky at bottom, and assume a more robust firm growth, particularly the pineapple, and are thereby more capable of producing large fruit.

After having determined on the dimensions as to length and width, the foundations of the walls should be set out accordingly of brick-work, allowing due width at bottom to support the flues a foot wide, wholly on the brick bases; detached an inch or two from the main walls; then setting off the back or north wall a brick and a half or two bricks thick, and the front and end walls nine inches, carrying up the back wall from ten to fourteen feet high; but those of the front and ends only from about two feet to a yard; taking care, in carrying up the walls, to allot a proper space for a door-way, at one or both ends, towards the back part; setting out also the furnace or fire-place of the flues in the bottom foundation, towards one end of the back wall behind, formed also of brick-work, made to communicate with the lowermost flue within. But when of great length, as forty feet or more, a fire-place at each end may be necessary; or, if more convenient, may have them in the back part of the end walls, or both in the middle way of the back wall; each communicating with a separate range of flues; in either case, forming them wholly on the outside of the walls, about twelve or fourteen inches wide in the clear, but more in lengthways inward; the inner end terminating in a funnel to communicate internally with the flues, fixing an iron-barred grate at bottom to support the fuel; calculated for coal, wood, peat, turf, &c. An ash-hole should be made underneath. The mouth or fuel door should be about ten or twelve inches square, having an iron frame and door fixed to shut with an iron latch as close as possible. The whole furnace should be raised sixteen or eighteen inches in the clear, finishing the top archways. Then continue carrying up the walls of the building regularly, and on the inside erect the flues close along the walls.

It is sometimes advantageous to have the flues a little detached from the walls, one, two, or three inches, that, by being thus distinct, the heat may arise from both sides, which will be an advantage in more effectually diffusing the whole heat internally in the house; as, when they are attached close to the walls, a very considerable

portion of the heat is ineffectually lost in the part of the wall behind. In contriving the flues, they should be continued along the front and both ends, in one range at least, in this order. But it is better if they be raised as high as the outward front and end walls, in one or two ranges, one over the other. On the tops of these may be placed pots of many small plants, both of the exotic and forcing kinds.

Thus proceed in the construction of the flues, making them generally about a foot wide in the whole, including six or eight inches in the clear, formed with brick-work, on edge; the first lower flue should communicate with the furnace or fire-place without, and be raised a little above it, to promote the draught of heat more freely, continuing it along above the intended level of the floor of the back alley or walk of the house the above width, and three bricks, on edge, deep, returning it in two or three ranges over one another, next the back wall, and in one or two along the ends, and front wall, as the height may admit; each return two bricks, on edge, deep, and tiled or bricked over. In the beginning of the first bottom flue a sliding iron regulator may be fixed, to use occasionally, in admitting more or less heat, being careful that the brick work of each flue is closely jointed with the best sort of mortar for that purpose, and well pointed within, that no smoke may break out; having each return closely covered with broad square paving tiles on the brick-work; covering the uppermost flues also with broad, thick, flat tiles, the whole width, all very closely laid, and joined in mortar. The uppermost or last range of flues should terminate in an upright vent or chimney at one end of the back wall; and where there are two separate sets of flues, there should be a chimney at each end. An iron slider in the termination of the last flue, next the chimney, may also be provided, to confine the heat more or less on particular occasions.

Sometimes, in very wide houses, in erecting the flues, to make all possible advantage of the fire-heat, one or more spare flues, to use occasionally, is continued round the bark-pit, carried up against the surrounding wall, but detached an inch or two, to form a vacancy, for the heat to come up more beneficially, and that by having vent, it may not dry the tan of the bark-bed too much; and in the beginning a sliding iron regulator may be fixed, either to admit or exclude the heat, as expedient; so that the smoke, by running through a larger extent, may expend its heat wholly in the flues before it is discharged in the chimney.

Great care must likewise be taken that neither

the fire-place or flues be carried too near any of the wood-work.

After this, proceed to set out the cavity for the bark-pit, first allowing a space next the flues for an alley or walk, eighteen inches or two feet wide all round, and then in the middle space form the pit for the bark-bed, six or seven feet wide, the length in proportion to that of the House, and a yard or more deep; inclosing it by a surrounding wall. It may either be sunk at bottom a little in the ground, raising the rest above, by means of the parapet wall; or, if there is danger of wet below, it should be raised mostly above the general surface. The surrounding wall should be nine inches, but a brick-wide wall is often made to do, especially that part which forms the parapet above ground. It should be coped all round with a timber plate or kirk, framed and mortised together, which effectually secures the brick-work.

The bottom of the pit should be levelled and well rammed, and if paved with any coarse material, it is an advantage in preserving the bark. And the path or alley round the pit must be neatly paved with brick or stone.

The glass-work for inclosing the whole should consist of a close-continued range of glass sashes all along the front, both ends, and roof, quite up to the back wall; each sash being a yard, or three feet six inches wide; and for the support of which, framings of timber must be erected on the brick-walling, conformable to the width and length of the sashes.

For the reception of the perpendicular glasses in the front and ends, a substantial timber plate must be placed along the top of the front and end walls, upon which should be erected uprights, at proper distances, framed to a plate or crown-piece above, of sufficient height to raise the whole front head high, both ends corresponding with the front and back; a plate of timber being also framed to the back wall above, to receive the sloping bars from the frame-work in front; proper grooves being formed in the front plates below and above, to receive the ends of the perpendicular sashes, sliding close against the outside of the uprights all the way along the front, or they may be contrived for only every other sash, to slide one on the side of the other.

And from the top of the upright framing in front should be carried substantial cross-bars or bearers, sloping to the top of the back wall, where they are framed at both ends to the wood-work or plates, at regular distances, to receive and support the sloping glass sashes of the roof, when placed close together upon the cross bars or rafters, and generally ranging in two or more

tiers, sliding one over the other, of sufficient length together to reach quite from the top of the upright framing in front, to the top of the back-wall. The cross bars should be grooved lengthways, above, to carry off wet falling between the frames of the sloping lights; making the upper end of the top tier of glasses shut close up to the plate in the wall behind, running under a proper coping of wood or lead, fixed along above close to the wall, and lapped down of due width to cover, and shoot off the wet sufficiently from the upper termination of the top sashes. Some wide Houses have, exclusive of the main slope sliding glass sashes, a shorter upper tier of glass fixed; the upper ends being secured under a coping as above, and the lower ends lapping over the top ends of the upper sliding tier, and this over that below in the same manner, to shoot the wet clear over each upper end or termination; likewise along the under outer edge of the top plate, or crown-piece in front, may be a small channel to receive the water from the sloping glass sashes, and convey it to one or both ends without running down upon the upright sashes, being careful that the top part behind be well framed and secured, water-tight, and the top of the back wall finished a little higher than the glasses, with a neat coping the whole length.

The bars of wood which support the glasses should be neatly formed, and made neither very broad or thick to intercept the rays of the sun. Those, however, at top, should be strong enough to support the glasses without bending under them. In wide Houses uprights are arranged within at proper distances, to support the cross rafters more perfectly.

In respect to the glass work in the sloping sashes, the panes of glass should be laid in putty, with the ends lapping over each other about half an inch; the vacancies of which are in some closed up at bottom with putty, others leave each lapping of the panes open, in order for the air to enter moderately, and that the rancid vapours arising from the fermentation of the bark-bed; &c. within, may thereby be kept in constant motion without condensing much; and also that such as condense against the glasses, may discharge itself at those places without dropping upon the plants. The upright sashes in front may either be glazed as above, or the panes laid in lead work; being very careful to have the glazing well performed, and proof against wet.

The doors should have the upper parts sashed and glazed to correspond with the other glass-work.

On the inside the walls should be plastered,

plastered, and white-washed; and all the wood-work within and without, painted white in oil colour.

Ranges of narrow shelves for pots of small plants may be erected where most convenient, some behind, over the flues, a single range near the top glasses towards the back part, supported either by brackets suspended from the cross bars above, or by uprights erected on the parapet wall of the bark-pit. A range or two of narrow ones may also be placed occasionally along both ends above the flues.

In wide Houses, where the cross-bars or bearers of the sloping or top glass sashes appear to want support, some neat uprights, either of wood or iron, may be erected upon the bark-bed walling, at convenient distances, and high enough to reach the bearers above.

On the outside behind should be erected a close shed the whole length, or at least a small covered shed over each fire-place, with a door to shut, for the convenience of attending the fires; but the former is much the best, as it will serve to defend the back of the Houses from the outward air, and to stow fuel for the general use of them, also for garden-tools, and all garden utensils when not in use, to preserve them from the weather; as well as to lay portions of earth in occasionally, to have it dry, for particular purposes in winter and early spring.

Sometimes Hot-houses are furnished with top covers, to draw over the glass sashes occasionally, in time of severe frosts and storms; and sometimes by slight sliding shutters, fitted to the width of the separate sashes; but these are inconvenient, and require considerable time and trouble in their application. At other times they are formed by painted canvass, on long poles or rollers, fixed lengthways along the tops of the Houses, just above the upper ends of the top sashes, which, by means of lines and pulleys, are readily let down and rolled up.

In the annexed plate is contained the front elevation and ground plan of an improved House of this sort, which has been found to answer well in practice.

Fig. 1. Front elevation.

Fig. 2. Ground plan.

Fig. 3. Section.

A plan for another kind of improved Hot-house has been suggested by Dr. James Anderson, for which he has taken out a patent. It produces its effects chiefly by the heat of the sun, without the aid of flues, tan-bark, or steam. This improvement extends to every sort of Hot-house; and the advantages of such Hot-houses are, according to the statement of the doctor,

1st. That "in every kind of temperature, if the works are to be erected new from the foundation, few cases can occur in which they may not be so placed as that the *whole* heat required may be obtained without occasioning the expenditure of *one shilling* for fuel; but in the most unfavourable cases that can occur, the expenditure of fuel will *not* amount to *one tenth* part of what is now universally employed for producing similar effects."

2d. That "in a Vinery, for example, where the grapes are not meant to be forced farther than to ripen from the middle of June to the end of July, as the season may be, no fuel will in any case be required, the whole effect being produced by the heat of the sun alone."

3d. That "where the grapes are to ripen in April or May, some artificial heat will be wanted; but the quantity of fuel, even in this case, will be so inconsiderable, that in a house which produces, on an average of years, under ordinary good management, not less than *ten thousand* full-sized bunches of grapes, and fifteen hundred pots of strawberries, or other such plants, the consumption of fuel will not exceed *half a London chaldron of coals*; and so in proportion for those of larger extent."

4th. That "in the Pinery and Stove the expenditure of fuel will be diminished in a proportionate degree; while, at the same time, the use of *bark* (or of *steam*, as a substitute for the heat of *tan*) will be entirely dispensed with; which, in many situations, will be the saving of much expense."

5th. That "these savings of expenditure will be effected not only without any detriment to the pines and other plants, but with great advantage to them all; for, in consequence of these improvements, those diseases which so much weaken and often destroy the most valuable plants, the damp in particular, will be entirely removed, and vermin in a great measure annihilated; the plants too, in consequence of the ventilation that may be at all times given them at pleasure to any degree that shall be thought proper (without varying the temperature from that degree which may be deemed most salutary to the plants, at the same time that it may be changed at will from moist to dry, or the reverse), may be kept in a state of perpetual health and luxuriance that has been hitherto unknown in these repositories." And,

6th. That "all these effects will be produced by such a simple apparatus, and that so adapted as to moderate of itself extremes of every sort, that it will become a matter of much less nicety and trouble to the gardener than at present; as he may safely be absent for a much longer time,

and thus the accidents which originate from negligence less frequently occur."

These houses are made almost wholly of wood and glass. The base is a frame of wood, which rests horizontally upon posts fixed firm in the ground, to which the frame is screwed by strong iron screws; the whole being so constructed as to admit of being taken down and removed at pleasure without violence, merely by undoing the screws. They are capable of being formed of any dimensions. A full explanation of their nature, and the principles on which they produce their effects, may be seen in the doctor's work on the "Patent Hot-house."

Hot-houses on this plan are constructed by George Byfield, esq. architect, Craven-street, Strand, London; and Mr. Samuel Butler, Hot-house-builder, Little Chelsea.

Nursery and Succession Houses.—In addition to these Hot-houses, others of smaller dimensions, for striking and raising the young plants in, and as Succession Houses for receiving them into afterwards, when of a year's growth, to bring them forward to a proper size for being used as fruiting plants, are necessary, especially where the pine-apple is cultivated upon an extensive scale, in order to afford full room in the large Houses for the fruiting plants.

These Houses may be erected either as appendages to the main house, or detached at a little distance, as most convenient. When the situation admits, it is however more convenient and ornamental to join them in a line with the main House, one at each end. They are formed nearly of the same construction, only smaller both in length, width, and height.

Nursery-House.—This is sometimes formed in the manner of a common detached bark-pit, without any upright glasses in front, having a wall all round, five or six feet behind, gradually sloping at each end, to about four feet in front, and with only sliding glasses at top. Its dimensions must vary according to the extent of plants. It is often termed simply the pit, as the whole internal space in length and width is allotted entirely as a pit for a bark-bed, without any walk within, or door for entrance, the necessary culture being performed by sliding open the glasses at top, the flues for the fires being formed in the upper part of the back wall, above the surface height of the bark-bed. They may, however, be formed in the manner of the Houses.

Succession House.—This should be constructed with erect glasses in front, and sloping sashes at top, with a door for entrance, and an alley or walk next the back wall; or, what is better, continued round the bark-pit. And where joined to the end of the House, it may be di-

vided from it by a sliding glass partition, having a separate furnace and flues, as the young pine plants do not at all times require the same degree of fire-heat as the older pines. The dimensions must vary according to circumstances and the number of plants. See STOVE and GREEN-HOUSE.

HOT-HOUSE PLANTS, such of the tender exotic or other kinds as require this sort of house for their growth, protection, and preservation in this climate. See STOVE PLANTS.

HOT-WALL, a range or extent of brick or stone walling, fronted with glass-work, so as to inclose a space of several feet in width, constructed with internal fire-flues, &c. designed for forcing fruit-trees to early production.

Walls of this nature are mostly ranged lengthways, east and west, to front the full sun; having the south side, or that exposed to the sun, covered by a frame-work of glass, the whole length and height, including a space of but moderate width, as four, five, six, or eight feet, for one row of trees behind, trained in the wall-tree order, and extended from twenty or thirty, to forty, fifty, or a hundred feet in length; or of greater width, as ten, twelve, or fifteen feet, in the forcing-house manner, to admit of a range of trained trees behind, and others of lower growth forward; and, in either having internal flues for fire-heat in the main wall, and continued round along towards the front glass, or sometimes ranged longitudinally along the middle space. Some Hot-walls have likewise the front inclosure of glass-work, of sufficient width to admit of forming an internal pit, from four to five or six feet in width, the length of the erection; in which to make a bark-bed, or sometimes a dung hot-bed, or occasionally dung below, and bark above, to assist, in conjunction with the fire heat of the flues, in warming the internal air.

In either method, a border of good mellow, loamy, or other fertile earth, of proper width, is formed against the main wall, in which to plant the trees. Where there is no bark-bed, the whole bottom space is formed of good earth, having a narrow inclosure of glass, four, five, or six feet, to have only a range of trees next the wall, trained as wall-trees, or espaliers; or sometimes made wider, to have wall trees behind, trained to the height of the wall, and others trained in lower growth, in the internal space forward, either in the espalier manner, or as small dwarf-standards, or sometimes as horizontal dwarfs. See DWARF TREES.

When these are made of wide dimensions, either to admit of a bark-pit, or to have the whole internal bottom space of earth with trees

against the wall, and others planted forward between these and the glasses, they may properly be considered as forcing-houses.

In proper Hot-walls, as such as have narrow inclosures of glass from four to five or six feet in width, containing only one range of trees, they may be trained towards the wall upon trellis-work, where there is a range of flues immediately next the wall; but where all the flues are ranged forward, the trees may be trained close to the wall. See FORCING FRAME.

In the annexed plate is seen the ground-plan, section, and elevation of an improved wall of this kind, in which fig. 1. is the ground plan, fig. 2. longitudinal section, and fig. 3. transverse section.

HOUND'S-TONGUE. See *CYNOGLOSSUM*.

HUMBLE PLANT. See *MIMOSA*.

HUMULUS, a genus containing a plant of the hardy twining perennial kind.

It belongs to the class and order *Dioecia Pentandria*, and ranks in the natural order *Scabridæ*.

The characters are: that in the male the calyx is a five-leaved perianthium: leaflets oblong, concave, blunt: there is no corolla: the stamina have five capillary filaments, very short: anthers oblong: in the female the calyx is an universal involucre, four-parted, sharp: partial four-leaved, ovate, eight-flowered: to each flower a perianthium, one-leaved, ovate, very large, outwardly flat on one side, converging at the base: there is no corolla: the pistillum is a very small germ: styles two, subulate, patulous: stigmas sharp: there is no pericarpium: calyx inclosing the seed at the base: the seed roundish, covered with a coat.

The species is *H. Lupulus*, the Hop.

It has a perennial root: the stems weak and twining, not climbing by tendrils, but ascending a prop, trees or shrubs in a spiral, always with the sun, that is, from right to left, or from east to west by the south: these stems are angular, striated, and rugged, with very minute prickles: the leaves opposite in pairs (or sometimes in threes), the upper ones heart-shaped, the lower three-lobed (or sometimes five lobed), serrate, dark green above, pale green beneath, on long petioles; which, as well as the leaves themselves, are rugged with minute prickles: the stipules two or four, cordate, bifid at each joint: the flowers greenish yellow; the males on branched peduncles; the females on a distinct plant, peduncled, in pairs, in form of a cone or strobile, composed of ovate, membranaceous scales, tubular from being rolled in at the base, and two-flowered, each containing one (sometimes two) seed, of a brown bay co-

lour, of a globular form a little flattened, surrounded with a sharp rim, and compressed at the tip. It is a native of most parts of Europe, flowering in June.

There are Hop plants, which bear male flowers only, growing in long clusters; and Hop plants which bear female flowers only, produced in roundish, scaly, leafy clusters. The latter is the only sort cultivated, and which the Hop planters distinguish into, Early White, Long White, Oval, and Square Garlick Hops.

Culture. These plants are increased by cuttings of the suckers immediately from the roots within the earth, every part of which will grow, making them six or seven inches long, each having three or four buds or eyes, for emitting shoots. They may be taken from the roots of the plants of any old plantation. Care should be taken to choose good sorts, and such as are good bearers, trimming each set from all parts of the old vine, and any hollow or bad part.

They may also be propagated by layers of the young shoots in summer, cutting off their tops at the time of laying; they will soon root and form sets for next spring.

The plants or sets should be all of a sort, not early, middle, and late kinds planted together, which, by ripening at different times, would occasion great trouble in gathering the produce.

The Early White Hop, which comes first, is a fine Hop, but an indifferent bearer. The Long White Hop comes next, and is a good bearer. The Square Garlick Hop comes latest, but is a plentiful bearer, though a coarser Hop than the others.

The ground for this purpose should be well dug over, and rendered perfectly fine in the mould, as well as smooth and level on the surface.

When the land is thus prepared, having the sets ready, proceed to plant them by line, in straight rows, six or eight feet distant, and the same distance in each row, in the quincunx order. A long line should be provided to reach quite across the ground, on which, at every six or eight feet, a knot or small bit of rag should be tied; then stretching the line, and having a quantity of sharp-pointed sticks, place one down at each of the marks, and at each a hole should be dug a foot and a half wide, or more, and filled up again with the earth and some rotten dung laid on for the purpose, raising it into a sort of hillock, for the reception of the plants, which should be planted four or five in each, by means of a dibble, putting them in within a little of the tops, one in the middle, and the others at equal distances round it, pressing the

mould well round them, and covering them with fine mould as they are finished off.

The proper season for performing this business is in the early spring, as in the latter end of March or beginning of April.

When the plantation has been thus formed, the next care is to keep it clean from weeds, by frequent hoeing. The first operation should be performed in May, choosing dry weather; and as the work proceeds, a little mould should be drawn round about each hill to form a greater body of earth immediately about the plants, continuing the hoeings during the summer, as there shall be occasion.

The plants shoot forth into tolerably strong vines early the same year; so that in May small poles may be placed to each hill for them to run up on, and they will produce a few hops the same year; though some do not pole them at all the first season, which is a better practice, only twist the vine into a bunch in June, at the top of each hill, regardless of any crop, as it is apt to weaken the young plants.

In the spring following, in February or March, it is necessary to dress or prune the hops; when the ground must be dug or ploughed, and the earth about the hills of plants be removed from the stocks or roots, clearing it quite away from the tops of the principal roots with an iron picker, for the convenience of pruning close to the head of the stock; then with a sharp knife trim off all the shoots of last year, or the remaining part of them, close to the heads of the stocks or sets; clearing away also all young suckers, and directly trim in the earth around each hill, and cover the stocks with mould two or three inches thick. The same process must be repeated annually.

After this the plants soon shoot forth into vine, or bind; when long poles, about fifteen or twenty feet in length, must be placed for them to run upon. April, or the beginning of May, when the shoots are a foot long, is the proper season for this work: three poles must be set to each hill, around the outside, let deep into the ground, by making holes for them with an iron crow, so as to place them with their tops inclining a little outward from each other, to keep the plants from entangling, and a space between two of them be left open toward the south, to admit the sun more freely.

When thus poled, they naturally twine themselves about the poles, directing such with the hand as do not readily catch hold of themselves, turning them the way of the sun's apparent motion, tying them loosely with dried rushes or other soft bandages, training two or three vines to each pole; all above that number being plucked up, if the plantation be old; but

if young, wrap them up together in the middle of the hills.

The next work is that of summer-digging, which should be done in the beginning of June. This is digging about the hills, and casting up some fine earth around, and upon each; which is sometimes repeated again the beginning of July, to make all the hills of a proper substance, for the better nourishing of the plants. And after the plants are grown up, where any of them are found under-poled, taller poles must be placed near those that are too short, to receive the vines from them; for, unless they have due length of pole, they will not yield a full crop; and if the vines are very strong and over-top the poles, it is common to strike off the heads of the shoots with a switch, whereby they throw out many lateral branches, well charged with clusters of fruit. In July they blow, and towards the end of August begin to ripen; the signs of which are, the bunches of fruit imparting a strong hop-like scent, becoming dry and hard to the touch, and the brownish colour of the seed. They are then fit for gathering, when they should be picked with all possible expedition; for a sudden storm of wind, or great rains, would do considerable damage, by breaking down the vines, and discolouring the Hops. This work must be performed in dry weather, if possible. And a certain number of hills in a square space is to be cleared at a time, generally about eleven, and a large square bin, or wooden frame, eight feet long by three broad, having a cloth within, hanging on tenter-hooks, is to be placed in the centre to receive the Hops; then proceeding by cutting up the vines of the above number of hills, and pulling up the poles, using a wooden instrument like a lever, having at one end a forked piece of iron, with teeth on the inside, which will readily raise them out of the ground; then laying two poles at a time across the bin, two or three persons standing on each side, in order to pick the Hops into it, picking them very clean without leaves and stalks; and as the bin is filled, it must be emptied two or three times a day, as there may be occasion, into a Hop-bag, and carried to the kiln to dry. This is the same as a malt-kiln, being covered with a hair cloth, on which to spread the Hops, which should be spread ten or twelve inches thick: a charcoal heat is commonly used; continuing an even steady fire, not fierce, but rather increased by degrees. In about nine hours the Hops should be turned, and in two or three hours more they may be taken off: by that time the brittleness of their stalks, and easy falling off of the leaves, determine them to be sufficiently dried.

They are then to be carried into dry upper rooms, to lie three or four weeks to toughen; otherwise they would become powder in the operation of bagging.

This is performed in large bags, made of about four eils and a half of ell-wide coarse cloth; about a handful of Hops being first tied into each corner at bottom, to serve as handles; the bag is then fastened to a hole of due width in the floor, made for that purpose, having a hoop fastened to the mouth of the bag, on which it rests on the edges of the hole; then a person puts the Hops into the bag, while another is continually treading them down, till the bag is full; the bag is then unfastened from the hoop, and let down; and the mouth closed up, tying a handful of Hops also in each corner, as in the bottom part; they are then ready for market, &c.

A plantation of Hops will continue in good bearing several years, provided the ground is properly manured; for which the proper manure is well rotted dung, or a compost of dung and earth, prepared some time for that purpose; and of either, from about twenty to forty cart-loads are the common allowance for an acre; the former quantity is generally allowed when dung is scarce, laying it only along the hills of plants to be dug in in winter or spring; but the best way is to allow about forty loads, and dig or plough it in any time from October till March; as such a dressing need not be repeated but once in two or three years, or thereabouts.

After the ground is cleared every year from the Hops, care should be taken of the poles, which, if they could be laid under any covered place, it would greatly preserve them; but for want of such convenience, they are usually placed in parcels upright in the open air, first fixing three or six poles firmly in the ground, in a triangular manner, wide at bottom, and tied together at top; then setting as many of the rest of the poles about them as may seem convenient. And as the poles decay, new ones must be provided. These may be of any wood; but the sorts commonly used are ash, birch, maple, sycamore, willow, poplar, and chesnut. It requires about three thousand poles to an acre, allowing three to each hill.

These plants are seldom cultivated in the garden, but as climbers for the purpose of affording ornament and variety, as they readily twist round any support to the height of twenty feet or more.

HURA, a genus furnishing a plant of the exotic tree kind, for the stove.

It belongs to the class and order *Monocotyledon*

Monadelphia, and ranks in the natural order of *Tricoccoe*.

The characters are: that in the male flowers the calyx is an ament from the divarication of the branches, oblong, drooping, covered with sessile, spreading florets: scales oblong: perianthium within each scale of the ament, cylindric, two-leaved, truncate, very short: there is no corolla: the stamina have a cylindric filament, a little longer than the calyx, peltate at the tip, rigid, below the tip twice or thrice verticelled with tubercles: anthers two, immersed in each tubercle, oval, bifid: female flower in the same plant: the calyx is a one-leaved perianthium, cylindric, furrowed, truncate, quite entire, closely surrounding the germ: there is no corolla: the pistillum is a roundish germ, within the calyx: style cylindric, long: stigma large, funnel-shaped, plano-convex, coloured, twelve-cleft, blunt, equal: the pericarpium woody, orbiculate, or globular-flattened, torose, with twelve furrows, twelve-celled: cells dissilient, crescent-shaped, with an elastic dagger point at the end: the seeds solitary, compressed, sub-orbiculate, and large.

The species is *H. crepitans*, Sand Box Tree.

It rises with a soft woody stem to the height of twenty-four feet, dividing into many branches, which abound with a milky juice, and have scars on their bark, where the leaves have fallen off. The branches are garnished with heart-shaped leaves; those which are biggest are eleven inches long, and nine inches broad in the middle, indented on their edges, having a prominent midrib, with several transverse veins from that to the sides, which are alternate; these stand upon long slender footstalks: the male flowers come out from between the leaves, upon peduncles which are three inches long; they are formed into a close spike, or catkin, forming a column, lying over each other like the scales of fish. The female flowers are solitary, and very near the ament, the leaves are alternate, and accompanied by caducous stipules; the petiole is glandular above; the younger leaves are involuted. The fruit is curious in its structure; and the tree, when it grows well, spreading and shady. It is a native of the Spanish West Indies.

Culture.—This plant is increased by sowing the seeds procured from abroad, in the early spring, in pots filled with rich earth, plunging them in a mild hot-bed of bark. When the plants have attained a few inches growth, they should be removed into separate pots of a small size, watering them, and replunging them in the bark bed of the stove, where they must be constantly kept, being occasionally removed

into larger pots, and sparingly watered in the winter season.

When thus managed, they will attain twelve or fifteen feet in growth in this climate, and often afford flowers.

They afford ornament and variety in the stove collections.

HYACINTHUS, a genus containing plants of the bulbous-rooted flowering perennial kind.

It belongs to the class and order *Hexandria Monogynia*, and ranks in the natural order of *Liliaceæ*.

The characters are : that there is no calyx : the corolla is monopetalous, campanulate : border six-cleft, reflex : nectary, three honeyed pores, at the tip of the germ : the stamina have six awl-shaped filaments, shorter : anthers converging : the pistillum is a superior germ, round-three-cornered, three-furrowed : style simple, shorter than the corolla : stigma obtuse : the pericarpium is a roundish capsule, three-sided, three-celled, three-valved : the seeds in pairs (generally), roundish.

The species cultivated are : 1. *H. orientalis*, Eastern or Garden Hyacinth ; 2. *H. non scriptus*, Common Hyacinth, or Harebells ; 3. *H. cernuus*, Bending Hyacinth ; 4. *H. serotinus*, Late-flowering Hyacinth ; 5. *H. amethystinus*, Amethyst-coloured Hyacinth ; 6. *H. muscari*, Musk Hyacinth ; 7. *H. monstrosus*, Feathered Hyacinth ; 8. *H. comosus*, Purple Grape Hyacinth ; 9. *H. botryoides*, Blue Grape Hyacinth ; 10. *H. racemosus*, Clustered Grape Hyacinth.

The first has a large coated bulb, viscid, and of a sweetish taste, from the bottom of which spring the roots, which are long round fibres, of a middling thickness ; from the middle of it a single naked stem or scape ; and from the top six, seven, or more leaves : the leaves are broadish, keeled, pale green at bottom, but of a darker green towards the end : the scape is a long span in height, smooth, roundish, pale green below, but tinged with brown towards the top : from the middle of this to the top come out the flowers one above another, not pointing the same way, as in the Harebell, but standing on different sides of the stalk ; three, four, or five, to twelve or more in number, each nodding on pedicels, half an inch in length, usually of a very dark green colour, and having a pair of small bractes at the base : the corolla is near an inch in length, almost cylindrical except at the base, where it swells or bellies out, and at the top the segments are turned back a little : these flowers have a very sweet smell, and are much valued for the variety of their colours, as pure white, white tinged with blue, all shades of blue from these to the dark

violet, and all shades of red purple from the faint blush to the deep red ; they are also sometimes yellow. It is a native of the Levant ; flowering in March and April.

There are varieties with single white flowers, with double white flowers, with red single and double flowers, with flesh-coloured single and double flowers, with blue single and double flowers, with purple-blue single and double flowers, with flesh-coloured single and double flowers, with yellow flowers, with double white flowers, with red eyes or middles, with double white with purple eyes, with double white with flesh-coloured eyes, with double white with yellow eyes, with double agate-blue, with double and single porcelain-blue, with double and single violet-coloured flowers.

There are also many intermediate varieties which have been obtained from seed, and by which many new ones of the above principal sorts are annually gained ; each variety being distinguished either by the name of the place where first raised, the person who raised them, or that of illustrious personages, as the greatest kings, the bravest generals, the most famous poets, the celebrated ancient historians, and gods and goddesses.

It is this species and varieties that are commonly esteemed and cultivated by florists.

The chief properties which distinguish the good Double Hyacinth are, that the stalk be tall, strong, and upright : the flowers or bells sufficiently numerous, each suspended by a short strong peduncle, in a horizontal position ; the whole having a compact pyramidal form, with the crown or uppermost flower perfectly erect : the flowers should be large, and well filled with broad bold petals, appearing to the eye rather convex, than flat or hollow : they should extend to about the middle of the scape or stalk : the plain colours should be clear and bright, strong ones being in general preferred to pale colours, and such as are mixed should blend with elegance.

In the second species the root is roundish, about the size of a nutmeg : the scape from six inches to a foot in height, upright, round, smooth, and solid, bowed down when it begins to flower : the leaves are four, six, or sometimes more, only half the length of the scape, and about half an inch broad, keeled, hollow, smooth, shining, grass green, flaccid, bending downwards, ending in an acute point : the flowers are in a long raceme or spike, from eight to twelve, often more, all pointing one way, pedicelled, pendulous, sweet-smelling, blue or violet colour, varying to white and flesh-coloured, six-parted to the very base. It is a native of France.

The third agrees with the first sort in habit

and appearance; but it is smaller, and differs in having the leaves more linear or less lanceolate, and more erect; the raceme is more nodding; the corollas flesh-coloured, not blue, rounder, with the sides of the petals less spreading, flat at the base, not marked with a raised line on the back, and less rolled back (though still reflex) than in that. It is a native of Spain.

The fourth species has an ovate-conical, solid bulb, covered with brown skins: the scape single, a foot high, and smooth: the leaves channelled, sheathing the scape at the base, shorter than the scape, sharp at the end: the flowers in a raceme, all pointing the same way, drooping a little; each on a short peduncle, with an awl-shaped bracte at the base: the corolla is of a dull greenish red colour. When the flowers first appear, they are of a light blue, but fading to a worn out purple colour. It is a native of Spain; flowering here in June.

In the fifth the root is the size of a small olive, covered with a brown skin: the leaves five or six, longer and narrower than in the first sort, striated and keeled, lying mostly on the ground: the scape slender, a long span in height, round, smooth, glaucous, having six or seven flowers at top (sometimes twelve or more), nodding, on pedicels half an inch in length; they are bright blue, smaller than those of the first sort, without any scent. They are smaller and of a deeper blue than the above.

Most of these have white stripes and edges; and they vary to pure white, and a fine pale red colour, with deeper-coloured veins running along the three outer segments. It was formerly known by the name of *Coventry Blue Hyacinth* by gardeners. It is a native of Spain, flowering in April and May.

The sixth species has pretty large, oval, bulbous roots, from which arise several leaves, which are about eight or nine inches long, and half an inch broad; incurved a little on their sides, and end in obtuse points; these embrace each other at their base; out of the middle of these, the stalk which sustains the flowers arises; it is naked below, but the upper parts are garnished with small flowers growing in a spike; these have ovate pitcher-shaped petals, which are reflexed at their brim, and are of an ash-coloured purple, seeming as if faded, but have an agreeable musky scent: the stalks do not rise more than six inches high. Where they are in quantity, they perfume the air to a considerable distance. It is a native of the Levant, flowering in April.

There are varieties with the same coloured flowers on the lower part of the spike, but larger, and more of the purple cast; and those on the up-

per yellow, with a very grateful odour, and with very large yellow flowers.

The seventh has a large bulbous root, from which come out several plain leaves a foot long, and about half an inch broad at their base; they are smooth, and end in obtuse points: the flower-stalks rise near a foot and a half high; are naked at the bottom for about seven or eight inches, above which the panicles of flowers begin, and terminate the stalks: the flowers stand upon peduncles which are more than an inch long, each sustaining three, four, or five flowers, whose petals are cut into slender filaments like hairs; are of a purplish blue colour, and, having neither stamina nor germ, do not produce seeds. It is a native of the south of Europe, flowering in May, after which the stalks and leaves decay to the root, and new ones arise in the spring following.

The eighth species has the root bulb as large as a middling onion, which is ovate, solid, and white, covered with a purplish skin: the leaves five or six, a foot (or eighteen inches) long, and three quarters of an inch broad at the base, diminishing gradually to a blunt point; (linear, channelled, bright green): the flower-stalk rises about a foot (or eighteen inches) in height (round, upright, smooth, glaucous green): the lower half is naked, but the upper part has a loose raceme of flowers, frequently for a foot in length: the lower flowers are further asunder; before they flower they are upright, but while they flower, and afterwards, they stand out horizontally on pedicels half an inch in length; their colour yellowish green, with blue or purple at the end: these are fertile. The upper ones smaller; leaves stand upright, forming a corymb, and are blue or violet, as also their long pedicels. It is a native of the South of Europe, flowering the end of April and beginning of May.

There are varieties, with white and with blue flowers. Mr. Curtis terms it the Two-coloured or Tassel Hyacinth. It is distinguished more by its singularity than beauty.

The ninth has the leaves three lines wide, straight on account of their short petioles: the spike has from twenty to thirty flowers: the teeth of the corolla are white, and the uppermost are small: and the leaves are rolled into a cylinder: the raceme (or spike) an inch long; the flowers nodding, sweet-smelling, scarcely longer than their upper pedicels. It grows naturally in the vineyards in France; and where once planted in a garden, it is not easily rooted out, as the roots multiply greatly.

There are varieties with blue, with white, and with ash-coloured flowers.

The tenth species has a small bulb: the leaves

are keeled, very narrow, a line or little more in breadth, cylindrical, on account of the weakness of their petioles loose and decumbent, rolled round and twisted in a variety of ways: the scape a span high, blue under the flowers, compressed at top, terminated by a close globular spike or raceme of from forty to fifty flowers, of a very dark blue, with a three-cornered white mouth; they are imbricated downwards, have very short peduncles, a sweetish smell, somewhat like new starch, or plums. It is a native of the South of Europe; flowering in April and May. Mr. Curtis terms it Starch Hyacinth.

Culture.—The first sort and varieties are all increased by planting the off-sets from the roots in the manner of other bulbous-rooted perennial plants; and by sowing the seed to produce new varieties.

They succeed best in a light soil, but will prosper in any common earth, particularly in moderate sandy ground, in a dry, open, sunny situation. These bulbs, if planted in strong or very moist land, are apt to rot in winter, or become diseased. Where, therefore, the soil of the flower-borders or beds is of a strong heavy quality, the part designed for Hyacinths should have light materials, such as any light sandy earth, from the surface of some common or other place; drift sea-sand, or any upper sandy soil, or light earthy compost; and where the soil of the borders, &c. is of a very light, sharp, sandy nature, a portion of light, mellow, loamy earth, and neat's dung, or well rotted dung of old hot-beds, make a fine compost surface mould for the Hyacinth, when mixed and laid on long enough before for the dung to be converted into mould.

The ground should be well wrought over as a preparation for the plants, one spade deep at least, raising the bed or border a little above the general level to avoid moisture; and raking the surface smooth and even.

The florists mostly prepare a compost for their rare kinds of Hyacinths, with light, sandy loam, or any sandy earth from a pasture-field, taking only the top spit, ten or twelve inches deep, adding about one third, from the surface, to one of drift or sea-sand, and the same quantity of rotten neat's dung; mixing the whole in a heap ridge-ways, in some dry sunny exposure, to lie several months, or if a year or more the better.

To the above material, some also add a quantity of rotten leaves of trees, thoroughly rotten tanner's bark, or any perfectly rotten earthy wood, or rotten saw-dust; all of which together greatly improve the composition: but as these are not always readily obtained, the other compost is frequently used with success. With these composts a bed is prepared in the beginning of au-

tumn, four feet wide and two deep, a cavity being dug out that width and depth, and filled up entirely with the composition, six inches above the common level, to allow for settling, leaving it a fortnight or a month to settle; when it is ready for the reception of the bulbs.

The curious in these plants never plant the fine sort two years together in the same bed or earth, without some previous renewal, as by planting them every year in a fresh bed, or fresh prepared compost, it greatly improves the size and beauty of the flowers.

The proper season for planting them is either in October, or the beginning of November; as those then planted shoot early in spring, and flower strong at their usual season; but those planted later in autumn, or continued out of ground till January and February, for a late bloom, flower weaker and with inferior beauty; the principal part should always be planted in the autumn.

When any of the common kinds are intended to be planted to adorn the open borders contiguous to the principal walks, or lawns near the habitation, to increase the variety in assemblage with other bulbous-rooted spring flowers, as early Tulips, Narcissuses, Anemones, Ranunculuses, &c. they should be disposed towards the front, more or less, in a varied order, in patches of three roots in each, three or four inches deep; and the patches may be from about one yard to three or four distance, letting them stand to take their chance, without any further care.

In planting the fine double sorts, four or five rows may be planted on each bed lengthways, about nine inches distant in each row, and about four inches deep, either in drills drawn the above depth, by dibble, or by bedding them in; and as soon as they are planted, in either method, the surface of the bed should be raked smooth and even.

The bulbs being thus planted, the choicest sorts should be protected in the beds occasionally during winter, from severe frost. They may be readily protected by a covering of straw, or any kind of dry strawy litter, three or four inches thick; or by arching the beds with hoops or rods, or with moveable arched frames of open work, covered with mats, the coverings being immediately removed when not wanted. The same caution should be continued in the spring.

When the flower-stems are advanced nearly to their full height, it is proper to support them, by placing a small stick, fifteen or eighteen inches long, close to each plant, being careful not to thrust it into the bulb, and to tie the stems neatly to each stick, by which the spikes of flowers will be preserved in an upright position.

When in bloom, the curious sorts may be preserved much longer in beauty, by being screened occasionally from the sun and rain, by a sort of awning or umbrella of mats or canvass; they should however be shaded only from the mid-day sun, from about ten to three or four o'clock, and only from excessive rains and boisterous winds.

But when the flowers begin to fade, all covering should be entirely removed, that the bulbs and increasing off-sets may derive all possible benefit from the free air, dews, &c.

When the season of flowering is over, the bulbs should be taken up, which in the florists' language is called lifting the roots. The fine sorts should be taken up at this period, to separate off-sets for increase, as well as to benefit the main bulbs, which will always flower stronger than such as are suffered to remain two or more years unre-moved.

The proper time for this work is in summer, soon after they have done flowering, when their leaves begin to turn yellow, as then the bulbs have had their full growth for that season, and should by no means remain longer in the ground.

Dry weather should be chosen, and a trowel, or small spade, is proper for lifting them, taking them up one by one, and breaking off the stem within an inch or two of its origin; then laying them in an airy room, out of the mid-day sun, to dry off the gross moisture very gradually, and to ripen the bulbs to a due hardness, when they appear of a purplish tinge; otherwise they are apt to rot.

When the bulbs are properly hardened and ripened, they should be taken up and separated from any off-sets, well cleared from earth, loose skins, and fibres at bottom; then, after exposing them a few hours in the sun, put up in boxes singly, or upon dry shelves out of the sun, to remain till the season for planting them again.

All the off-sets appearing about the main bulbs at the lifting season, are to be carefully separated from them, either as soon as they are taken up, or after the bulbs have lain to ripen, being kept separate, and planted in the early autumn, in beds by themselves, in rows six inches asunder, and two or three deep, where they should remain a year or two; then be taken up at the proper lifting season in summer, and managed as the large blowing roots.

In raising these bulbs from seed, which is practised by the curious, to obtain new varieties, to increase their stock; from the time of sowing, it will be four or five years before the bulbs produce flowers: the seed ripens in the summer,

which may easily be saved, by suffering some of the finest singles and half doubles to stand to ripen it in perfection.

The proper season for sowing it is in the beginning of autumn; when the plants will come up in the spring following. It grows freely in the open ground, in a bed or border of light earth; but when no great quantity is to be sown, it may be put into pots or boxes, which will be convenient to move occasionally to different situations at different seasons. In either method choose rich light earth, making the surface smooth, sowing the seeds evenly, and covering them an inch or an inch and a half deep: if they are sown in pots or boxes, let those be plunged to their rims in a dry place, and in November remove them either under a hot-bed frame to have occasional shelter in winter, or cover them at the approach of hard frost with some light dry litter, using the same precaution as for those sown in beds; but let them be fully exposed in all mild weather.

When they appear in the spring, first with very small leaves, they should be kept very clean from weeds, sifting a little earth over the bed in autumn, and in winter use the same precaution as before. In the second summer, when their leaves begin to decay, take up the young bulbs, to be planted out in nursery-beds, which may be done in August or September, planting them in small drills two inches deep, having the drills three or four inches asunder. In this situation they may stand two years, sifting half an inch of earth over the surface in autumn, and giving occasional coverings in winter: after this they are to be taken up at the usual lifting-season, and managed as the other bulbs, and planted in autumn where they are to flower.

The other species are capable of being increased readily, by planting the off-sets in the same manner as above, which all the sorts produce in great plenty, and which may be taken up every second or third year when the leaves decay, and the off-sets be separated and managed in the manner as the first sorts.

Blowing them in Water Glasses. — These bulbs may be brought to flower in winter and spring, by placing them in root-glasses of water, or in pots, or small boxes of sand, or light, dry, sandy earth, in the early autumn, and placing them in a warm apartment, or in a green- or hot-house; in all of which they will blow very agreeably, earlier or later in the above seasons, according to the time the bulbs are planted and introduced.

The glasses for this purpose are sold at the glass-shops, and many of the principal seed-shops and nurseries, at from five to nine shil-

lings per dozen; they are of the bottle kind, but with straight upright bodies narrowing a little upward gradually to the tops, where they terminate in wide, concave mouths, to contain each one root or bulb. They should be filled with soft, clear water, up to the necks, and a little way in the concavity of the mouths; one bulb placed in each glass, with the bottom or root part a little in the water, the top upright; and the bottles set either within a room window, which if towards the sun, will be of greater advantage, or placed on a chimney-piece, or shelves of a light room, where a fire is kept, to bring the bulbs forwarder in growth.

They soon put forth strong root-fibres down into the water, and push leaves and flower-buds at top, which advance regularly for flowering in their peculiar manner. The water should be renewed occasionally when it becomes foul or fetid, discharging the old, and immediately filling up the bottles with fresh water, which is all the culture they require. When the stalks and flower-spikes are considerably advanced, a neat small stick should be placed to each, to support it in an upright growth. But to obtain them in bloom at the most early period, some glasses containing the bulbs should be placed in a hot-house or forcing-house, &c.

In the glasses, the bulbs flower in about six, eight, or ten weeks, accordingly as they are placed. They continue three or four weeks in bloom.

By planting some bulbs in pots or neat boxes of light earth or sand in the autumn, and placing them in a dwelling-room, green-house, &c. they will flower at an early season.

But they flower most early, as has been just observed, in a hot-house, or forcing department, under glasses, worked either by fire or bark-bed heat, &c. Some middling small pots should be provided for this use, or small, neat, oblong boxes, six inches deep, filling them half way, or a little more, with dry light earth, or that of a sandy nature, or with sand; planting one, two, or three bulbs in each pot, according to the size; pressing the bottom gently into the earth, and filling up with more earth or sand over the crown of the bulbs; or, in boxes, several may be planted in each, in the same manner. When thus planted, place the pots or boxes in the house, giving moderate waterings with soft water, when the earth appears dry. They will flower in six or eight weeks. When the flowering is past, and the stalks and leaves decayed, the bulbs should be taken up, cleaning and drying them, and they may afterwards be planted in the full ground for the future year, to recover strength, and produce some good offsets.

The sorts generally used for glasses and pots, &c. are principally any varieties of the oriental kind, especially for blowing in water.

In procuring them, care should be taken to choose perfectly sound, firm bulbs, with the root part at bottom, full, plump, and firm.

They are all very beautiful and ornamental plants. The more hardy and common sorts in patches of five or six in the fronts of borders, clumps, and other parts; and the finer double sorts in beds, pots, boxes, and glasses.

HYDRANGEA, a genus containing plants of the shrubby and flowering perennial kinds.

It belongs to the class and order *Dicandria Digynia*, and ranks in the natural order of *Succulentæ*.

The characters are: that the calyx is a one-leaved perianthium, five-toothed, permanent, small: the corolla has five petals, equal, roundish, larger than the calyx: the stamina have ten filaments, longer than the corolla, alternately longer and shorter: anthers roundish, twin: the pistillum is a roundish germ, inferior: styles two, short, distant: stigmas blunt, permanent: the pericarpium is a roundish capsule, twin, two-beaked with the double style, angular, with several nerves, crowned with the calyx, two-celled, with a transverse partition, opening by a hole between the horns: the seeds numerous, angular, acuminate, very small.

The species cultivated are: 1. *H. arborescens*, Shrubby Hydrangea; 2. *H. hortensis*, Garden Hydrangea, or Chinese Guelder Rose.

The first has a spreading woody root, which produces several soft, pithy, woody stems, from three to four feet high; they are four-cornered when young, and have a green bark, but as they grow older they become taper, and have a light-brown bark: the leaves at each joint opposite, three inches long, and two broad near the base, pointed, serrate; they are deep green above, and pale underneath, with many transverse veins; the petioles are about an inch long: the flowers terminating in a cyme: the corolla small, white, having an agreeable odour. It is a native of Virginia, &c. flowering towards the end of July, and in August.

The second species has a fibrous root, much branched, whitish: the stems several, growing together, erect, shrubby, branched, round, with a smooth brown bark: the branches opposite, each pair crossing the others, round, smooth, leafy, green, with dark purple spots, flowering at the top: the leaves are opposite, spreading, and curved backwards, obtusely pointed, entire towards their base, bright green, pale beneath: foot-stalks short and thick, smooth, pale, channelled above: the cymes terminating, the size and

figure of the common Guelder Rose, and like that almost entirely composed of radiated abortive flowers, of a beautiful rose-colour, inodorous, green when young as well as in decay: the flower-stalks are variously subdivided, smooth, sometimes hairy: partial ones of a deep rose-colour, roundish. It is much valued on account of the great profusion of its elegant flowers. It is commonly cultivated in the gardens of China and Japan.

Culture.—The first is increased by slipping or parting the roots in the early autumn, and planting them out where the plants are to grow. It succeeds best in a moist soil, and requires no trouble but being kept free from weeds, by digging the ground about it in the winter. When the stems are destroyed in severe frosts, new ones are put forth in the ensuing spring.

The second sort is easily increased by planting cuttings of the young shoots, in pots of rich loamy earth, in the spring, plunging them in a moderate hot-bed. When they have stricken good root, they should be removed with balls of earth about their roots into separate pots, and be placed in the green-house.

Though this plant is capable of standing the open air in mild winters, in warm dry situations, it does not flower so well as in the green-house. Superfluous plants should therefore only be employed in this way.

These are ornamental plants; the former in the fronts of the clumps and borders, and the latter among green-house collections and other potted plants, where it produces a fine appearance.

HYDRASTIS, a genus affording a hardy perennial plant.

It belongs to the class and order *Polyandria Polygynia*, and ranks in the natural order of *Ranunculaceæ*.

The characters are: that there is no calyx: the corolla has three petals, ovate, regular: the stamina have numerous filaments, linear, compressed, a little shorter than the corolla: anthers compressed, blunt: the pistillum has numerous germs, ovate, collected into an ovate head: styles very short: stigmas broadish, compressed: the pericarpium is a berry, compounded of oblong acini, or granulations: seeds solitary, oblong.

The species is *H. Canadensis*, Canadian Yellow-root.

It has the root composed of thick fleshy tubers, of a deep yellow colour within, but covered by a brown skin, sending out fibres from several parts in the spring: it sends up one or two stalks about nine inches high, at their first appearance of a light green, but afterwards

changing to a purplish colour, and hairy towards the top. Each stalk has one or two leaves, the lower petioled, but the upper embracing; they are six or seven inches in diameter, and are deeply cut into three, four, or five lobes, which are irregularly serrate; they are of a light green in the spring, but change afterwards to a deep green, with some dark spots or marks, and after the flower is decayed turn to a purplish colour. The stalk is terminated by one flower, which is white, and of very short duration, seldom continuing above three or four hours after it is expanded. The fruit is red and succulent. It is a native of Canada, flowering in May and June.

Culture.—This plant may be increased by sowing the seed, as soon as the fruit is well ripened, in pots of pretty strong earth, protecting them from frost during the winter, and in the spring, when the plants appear, setting them in a shady situation till the autumn, when they may be planted where they are to remain.

It succeeds best in a moist shady situation, where it is not disturbed.

These plants serve to afford variety in such situations.

HYMENÆA, a genus containing a plant of the stove exotic kind.

It belongs to the class and order *Decandria Monogynia*, and ranks in the natural order of *Lomentaceæ*.

The characters are: that the calyx is a one-leaved perianthium, coriaceous: tube short, turbinate, compressed, permanent, with an oblique mouth: limb five-parted, almost regular, upright, deciduous: segments ovate, blunt: two opposite flattish, a little broader: two others concave, with one side narrower: the corolla five-petalled, inserted into the neck of the calyx, sub-papilionaceous, with the petals almost equal: banner, the two uppermost petals, obliquely ovate, obtuse, sessile, at the upper concave segment of the calyx: wings, two petals, similar, lateral, a little narrower: keel, the lowest petal, channelled and excavated, approximating to the wings, within the lower hollow segment of the calyx: the stamina have ten distinct filaments, awl-shaped, erect, bent down above the middle, very long, between the keel and the wings, inserted into the neck of the calyx: anthers linear, fixed by the back: the pistillum is a germ, sabre-shaped, compressed, pedicelled: style very long, bristle-shaped, bent down: stigma thickened, obliquely truncate: the pericarpium is a woody legume, very large, ovate-oblong, obtuse, one-celled, filled with farinaceous pulp: the seeds several (four to eight, large), ovate, wrapped up in pollen and fibres.

The species is *H. Courbaril*, Locust Tree.

It is a large spreading tree in its native situation: it has a large stem, covered with a russet bark, which divides into many spreading branches, garnished with smooth stiff leaves, which stand by pairs, their base joining at the foot-stalk, to which they stand oblique, one side being much broader than the other, the two outer sides being rounded, and their inside straight, so that they resemble a pair of sheep-shears; they are pointed at the top, and stand alternately on the stalk: the flowers are produced in loose spikes at the end of the branches, some of the short ligneous foot stalks supporting two, and others three flowers, which are composed of five yellow petals striped with purple, succeeded by thick, fleshy, brown pods, shaped like those of the garden bean. It is a native of the West India islands and America.

Between the principal roots of the tree exudes a fine transparent resin of a yellowish or red colour, which is collected in large lumps, and called gum Anime. It makes the finest varnish known, by being dissolved in the highest rectified spirits of wine.

Culture.—This is propagated by the seeds, which should be sown singly, in pots of a small size, filled with light earth, in the spring, plunging them in the bark hot-bed. When the plants have attained a little growth, they must be removed into the tan bed of the stove, where they must constantly remain, being managed as other tender plants, little water being given in the winter. Though the plants make much progress at first, they are soon at a stand, and only preserved with difficulty.

They afford variety in the stove.

HYOSCYAMUS, a genus comprehending plants of the annual, biennial, and perennial herbaceous and shrubby kinds.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Luridæ*.

The characters are: that the calyx is a one-leaved tubular perianthium, ventricose at bottom, with a five-cleft sharp mouth, permanent: the corolla one-petalled, funnel-form: tube cylindrical, short: limb from erect, spreading, half-five-cleft: segments obtuse, one broader than the others: the stamina have five awl-shaped filaments, inclining: anthers roundish: the pistillum is a roundish germ: style filiform, the length of the stamens: stigma headed: the pericarpium is an ovate capsule, obtuse, marked with a line on each side, two-celled, two capsules closely approximating, with a lid opening horizontally: receptacles half ovate, fixed to the

partition: the seeds numerous, unequal (irregular).

The species cultivated are: 1. *H. niger*, Black, or Common Henbane; 2. *H. reticulatus*, Egyptian Henbane; 3. *H. albus*, White Henbane; 4. *H. aureus*, Golden-flowered, or Shrubby Henbane; 5. *H. pusillus*, Dwarf Henbane; 6. *H. physaloides*, Purple-flowered Henbane; 7. *H. Scopolia*, Nightshade-leaved Henbane.

The first has long fleshy roots, which strike deep into the ground, and are branched: the bottom leaves are soft, deeply slashed on their edges, and spreading on the ground: the stalks which do not rise till the second spring, have leaves of the same shape, but smaller, and clasping, and are about two feet high; on the upper part are flowers standing on one side in a double row, sitting close to the stalk alternately. Martyn observes, that the whole plant is covered with unctuous foetid hairs: the corolla is yellow, or rather pale yellowish brown, beautifully netted with purple veins, and a dark purple eye or base: the shape is irregular, gradually tapering into the tube, with five prominent ribs on the outside; the upper segment is the largest, the rest gradually diminishing downwards: the upper incisions are shallow, the lowermost extending half way to the base, and much wider than the rest. It is biennial, forming the root and flower-leaves the first, and the stem and fructification the second season; a native of most parts of Europe, flowering in June. The root, herb, and seeds, are said to be poisonous.

There is a variety in which the corolla and anthers are of a pure brimstone colour, without any tinge of purple.

The second species rises with a branching stalk two feet high: the lower leaves are regularly cut on both sides into acute segments, which are opposite, but the upper leaves are entire: the flowers grow at the end of the stalk, in bunches: they are of a worn-out red colour, and shaped like those of the common sort, but their tubes are swollen. Martyn adds, that the whole plant is smooth, resembling the first, but the stem-leaves are ovate, repand, more smooth above; the floral leaves ovate, sessile, entire: the flowers on a very short peduncle: the corolla bell-shaped, red, beautifully netted with dark veins. It is annual, and a native of Egypt, &c. flowering in July.

The third resembles the first in most circumstances, but the leaves are more rounded or obtuse, petioled, sinuate, very soft, bearded with white hairs, as is also the stem: the flowers fewer, the lower ones on longer peduncles, but the upper flowers have very short ones: the calyx is green, five-toothed, and hairy: throat of

the corolla longer than in the first sort: limb revolute, five-cleft, with unequal segments: the capsule clothed with the calyx, membranaceous, knobbed with the protuberant seeds, ovate, ventricose at bottom, marked with a depressed streak on each side: the receptacle fungose, scrobiculate, ovate-oblong, plano-convex, fixed on both sides to the partition: the seeds very numerous, small, compressed a little, incurved or kidney-form, closely scrobiculate, whitish ash-coloured. It is annual, and a native of the south of Europe, flowering in August.

It has the corolla varying with the base dark purple, or green.

The fourth species is a perennial plant (biennial), with weak stalks, which require support: the leaves are roundish, acutely indented on their edges, and on pretty long foot-stalks: the flowers come out at each joint of the stalk; they are large, and of a bright yellow, with a dark purple bottom: the style is much longer than the corolla: the stem is hairy, and about a foot high: the petioles very hairy: the leaves lobed, toothletted: the peduncles at the side of the petioles, erect with the flower, but quite bent down when in fruit: the outer lobe of the corolla is larger than the rest, and the lower sinus is cut beyond the limb, and there the purple stamens with the very long pistil issue and hang down. It is a native of Candia, flowering most part of the summer.

It varies in size and the shade of the colour in the corolla.

The fifth is an annual plant, a hand in height: the stem oblique, brittle, undivided, having long hairs: the lower leaves entire, upper oblong, toothed, alternate, sparingly hairy, on petioles of the same length with themselves: the peduncles short on the outmost stem, each from the axil of two opposite leaves: the calyxes turbinate, ten-angled, almost the length of the corolla, and broader than its tube, spiny at top: the corolla yellow, with a dark throat, divided on the lower side beyond the limb: the stamens declining. It is a native of Persia, flowering in July.

The sixth species has a perennial root: the stems a foot high, simple, erect, round, rough-haired: the leaves alternate, petioled, cordate, lucid-green, veined, rough-haired underneath, the upper ones gradually larger: the flowers in bundles, terminating, peduncled: the calyxes very short, five-toothed, rough-haired: the corollas purplish, funnel-form, upright: the stamens a little shorter than the corolla, converging: the style the same length with the corolla: the stigma capitate, emarginate, whitish. It flowers early in spring, and is a native of Siberia.

The seventh has also a perennial root, transverse, knobbed, thick, irregular, branched, flexuose, the thickness of the human thumb: the stem herbaceous, annual, upright, round, smooth (scarcely more than a foot high, according to some, but even three feet in height, according to others), the thickness of the human finger, trifid and bifid, with dichotomous branches: (the branches only two, according to Linnaeus, spreading, and entirely simple; or, subtrichotomous, with a groove running down from the leaves:) the leaves ovate and oblong, the length of the human finger; the lower quite entire; the upper frequently moderately sinuate or repand: according to some, petioled, naked, somewhat wrinkled, spreading; on the stem alternate, solitary; under the forkings in threes, two of which approximate; on the branches alternate, but two together on the same tooth or base, one of which is a little less than the other: but, according to others, subovate or lanceolate, entire, except the lower ones, which in gardens at least are sinuate-toothed in front, veined, wrinkled, decurrent; the lower ones opposite, the rest scattered: the peduncles one-flowered, pendulous from the axils, weak, two inches long: the calyx smooth, five-toothed, permanent, wider than the fruit, and, as it were, inflated (bell-shaped, five-cleft, awnless): the corolla three times the length of the calyx, bell-shaped, slightly five-cleft, blunt, on the outside ferruginous, with a few pale streaks, within yellow, oblong, large, five-toothed, narrowing at the base into a short tube, yellowish purple, deciduous. It is a native of Idria in Friuli, flowering in the middle of April.

Culture.—They are all capable of being raised from seeds, by sowing them in the autumn in the situations where they are to stand. If the seeds be permitted to scatter, they also produce abundance of good plants.

In the fourth or shrubby sort, the seeds should be sown in pots, when perfectly ripened in the autumn, plunging them in a moderate hot-bed during the winter. When the plants have attained some growth in the spring, they should be removed into separate pots, and be replaced in the bed, due shade and water being given. It may also be increased by planting cuttings in a shady border of light earth, in the summer season, and when well rooted removing them into separate pots.

The only culture which the common sorts require is that of being kept clean from weeds, and properly thinned. The second sort succeeds best in a dry warm situation, or when planted in pots, and protected in the winter season. The fourth sort must be placed so as to have protec-

tion from frost in the winter season, and plenty of fresh air in mild weather.

All the sorts, except the second and fourth, may be introduced so as to afford variety in the borders and clumps of pleasure-grounds; but these two may be placed out among other more hardy potted sorts, or in collections of green-house plants, with good effect.

HYPERICUM, a genus furnishing plants of the shrubby and under-shrubby, hardy and tender kinds.

It belongs to the class and order *Polyadelphia Polyandria*, and ranks in the natural order of *Rotaceæ*.

The characters are: that the calyx is a five-parted perianthium: segments subovate, concave, permanent: the corolla has five petals, oblong-ovate, obtuse, spreading, wheel-shaped, according to the sun's apparent motion: the stamina have numerous capillary filaments, united at the base in five or three bodies: anthers small: the pistillum is a roundish germ: styles three (sometimes one, two, or five), simple, distant, the length of the stamens: stigmas simple: the pericarpium is a roundish capsule, with the same number of cells as there are styles: the seeds very many and oblong.

The species cultivated are: 1. *H. balearicum*, Warted St. John's-wort; 2. *H. Ascyron*, Great flowered St. Peter's-wort; 3. *H. Androsæum*, Common Tutsan; 4. *H. Canariense*, Canary St. John's-wort; 5. *H. hircinum*, Stinking Shrubby St. John's-wort; 6. *H. monogynum*, Chinese St. John's-wort.

The first rises with a slender shrubby stalk in this country, about two feet high; but in its native soil it acquires the height of seven or eight feet, sending out several weak branches of a reddish colour, and marked with scars where the leaves have fallen off: the leaves are small, oval, waved on their edges, and having several small protuberances on their under side: they sit close to the branches, half embracing them at the base: the flowers are terminating, large, bright, yellow. It is a native of Majorca.

The second species has a stem a cubit and half high, round, smooth, rufescent: the leaves are pale green, paler underneath, an inch long and half an inch wide, roundish, opposite: the flowers terminating: calyx green: corolla pale yellow, five times as large as in the common sort. It is a native of the Pyrenees.

The third has a perennial, thick, woody root, of a reddish colour, sending out very long fibres: the stems suffruticose or under-shrubby, ancipital two-edged or slightly winged on opposite sides, two feet high and more, branched towards

the top, of a reddish colour, and smooth: branches brachiate or decussated, spreading: the leaves opposite, sessile, ovate, entire, smooth, dark green, glaucous on the under side, netted with numerous projecting veins and nerves, which become through age ferruginous: on the stem they are two inches long, and an inch and half broad at the base; those on the branches are smaller, of different sizes, and some of them approaching to lanceolate: the flowers small for the size of the plant, disposed in a cyme: the peduncles round, smooth, usually two- or three-flowered, but sometimes one-flowered: the fruit an ovate capsule, assuming the appearance of a berry; at first yellowish green, then red or brownish purple, and lastly almost black when ripe. It is a native of the south of Europe.

The fourth species rises with a shrubby stalk six or seven feet high, dividing into branches at top: the leaves are oblong, set by pairs close to the branches, having a strong odour, but less than those of the fifth: the flowers terminating in clusters, very like those of the fifth. It is a native of the Canary islands, flowering from July to September.

The fifth rises with shrubby stalks three feet high, sending out small opposite branches at each joint: the leaves are oblong, ovate, placed by pairs, sessile, and having a rank smell: the flowers are in terminating bunches. It is a native of the south of Europe, flowering from July to September.

There are varieties, one larger, which is the common one: the other smaller.

The sixth has a root composed of many woody fibres, striking deep into the ground: the stems several, shrubby, near two feet high, covered with a purplish bark: the leaves stiff, smooth, about two inches long, and a quarter of an inch broad, opposite, sessile, of a lucid green on their upper surface, and gray underneath, having many transverse veins running from the midrib to the border: the flowers terminating in small clusters, each on a short peduncle. It is a native of China, flowering from March to September.

Culture.—The first and last sorts are more tender than the others, requiring the protection of the green-house in winter. They are capable of being increased by layers or cuttings. The former are made in the spring on the young shoots, which, when well rooted in the end of summer, may be taken off and planted out in separate pots. The cuttings of the young shoots may be planted in pots in the summer, and plunged in a hot-bed, and when well rooted, removed into separate pots.

the corolla longer than in the first sort: limb revolute, five-cleft, with unequal segments: the capsule clothed with the calyx, membranaceous, knobbed with the protuberant seeds, ovate, ventricose at bottom, marked with a depressed streak on each side: the receptacle fungose, scrobiculate, ovate-oblong, plano-convex, fixed on both sides to the partition: the seeds very numerous, small, compressed a little, incurved or kidney-form, closely scrobiculate, whitish ash-coloured. It is annual, and a native of the south of Europe, flowering in August.

It has the corolla varying with the base dark purple, or green.

The fourth species is a perennial plant (biennial), with weak stalks, which require support: the leaves are roundish, acutely indented on their edges, and on pretty long foot-stalks: the flowers come out at each joint of the stalk; they are large, and of a bright yellow, with a dark purple bottom: the style is much longer than the corolla: the stem is hairy, and about a foot high: the petioles very hairy: the leaves lobed, toothletted: the peduncles at the side of the petioles, erect with the flower, but quite bent down when in fruit: the outer lobe of the corolla is larger than the rest, and the lower sinus is cut beyond the limb, and there the purple stamens with the very long pistil issue and hang down. It is a native of Candia, flowering most part of the summer.

It varies in size and the shade of the colour in the corolla.

The fifth is an annual plant, a hand in height: the stem oblique, brittle, undivided, having long hairs: the lower leaves entire, upper oblong, toothed, alternate, sparingly hairy, on petioles of the same length with themselves: the peduncles short on the outmost stem, each from the axil of two opposite leaves: the calyxes turbinate, ten-angled, almost the length of the corolla, and broader than its tube, spiny at top: the corolla yellow, with a dark throat, divided on the lower side beyond the limb: the stamens declining. It is a native of Persia, flowering in July.

The sixth species has a perennial root: the stems a foot high, simple, erect, round, rough-haired: the leaves alternate, petioled, cordate, lucid-green, veined, rough-haired underneath, the upper ones gradually larger: the flowers in bundles, terminating, peduncled: the calyxes very short, five-toothed, rough-haired: the corollas purplish, funnel-form, upright: the stamens a little shorter than the corolla, converging: the style the same length with the corolla: the stigma capitate, emarginate, whitish. It flowers early in spring, and is a native of Siberia.

The seventh has also a perennial root, transverse, knobbed, thick, irregular, branched, flexuose, the thickness of the human thumb: the stem herbaceous, annual, upright, round, smooth (scarcely more than a foot high, according to some, but even three feet in height, according to others), the thickness of the human finger, trilid and bifid, with dichotomous branches: (the branches only two, according to Linnæus, spreading, and entirely simple; or, subtrichotomous, with a groove running down from the leaves:) the leaves ovate and oblong, the length of the human finger; the lower quite entire; the upper frequently moderately sinuate or repand: according to some, petioled, naked, somewhat wrinkled, spreading; on the stem alternate, solitary; under the forkings in threes; two of which approximate; on the branches alternate, but two together on the same tooth or base, one of which is a little less than the other: but, according to others, subovate or lanceolate, entire, except the lower ones, which in gardens at least are sinuate-toothed in front, veined, wrinkled, decurrent; the lower ones opposite, the rest scattered: the peduncles one-flowered, pendulous from the axils, weak, two inches long: the calyx smooth, five-toothed, permanent, wider than the fruit, and, as it were, inflated (bell-shaped, five-cleft, awnless): the corolla three times the length of the calyx, bell-shaped, slightly five-cleft, blunt, on the outside ferruginous, with a few pale streaks, within yellow, oblong, large, five-toothed, narrowing at the base into a short tube, yellowish purple, deciduous. It is a native of Idria in Friuli, flowering in the middle of April.

Culture.—They are all capable of being raised from seeds, by sowing them in the autumn in the situations where they are to stand. If the seeds be permitted to scatter, they also produce abundance of good plants.

In the fourth or shrubby sort, the seeds should be sown in pots, when perfectly ripened in the autumn, plunging them in a moderate hot-bed during the winter. When the plants have attained some growth in the spring, they should be removed into separate pots, and be replaced in the bed, due shade and water being given. It may also be increased by planting cuttings in a shady border of light earth, in the summer season, and when well rooted removing them into separate pots.

The only culture which the common sorts require is that of being kept clean from weeds, and properly thinned. The second sort succeeds best in a dry warm situation, or when planted in pots, and protected in the winter season. The fourth sort must be placed so as to have protec-

tion from frost in the winter season, and plenty of fresh air in mild weather.

All the sorts, except the second and fourth, may be introduced so as to afford variety in the borders and clumps of pleasure-grounds; but these two may be placed out among other more hardy potted sorts, or in collections of green-house plants, with good effect.

HYPERICUM, a genus furnishing plants of the shrubby and under-shrubby, hardy and tender kinds.

It belongs to the class and order *Polyadelphia Polyandria*, and ranks in the natural order of *Rotaceae*.

The characters are: that the calyx is a five-parted perianthium: segments subovate, concave, permanent: the corolla has five petals, oblong-ovate, obtuse, spreading, wheel-shaped, according to the sun's apparent motion: the stamina have numerous capillary filaments, united at the base in five or three bodies: anthers small: the pistillum is a roundish germ: styles three (sometimes one, two, or five), simple, distant, the length of the stamens: stigmas simple: the pericarpium is a roundish capsule, with the same number of cells as there are styles: the seeds very many and oblong.

The species cultivated are: 1. *H. balearicum*, Warted St. John's-wort; 2. *H. Ascyron*, Great flowered St. Peter's-wort; 3. *H. Androsæum*, Common Tutsan; 4. *H. Canariense*, Canary St. John's-wort; 5. *H. hircinum*, Stinking Shrubby St. John's-wort; 6. *H. monogynum*, Chinese St. John's-wort.

The first rises with a slender shrubby stalk in this country, about two feet high; but in its native soil it acquires the height of seven or eight feet, sending out several weak branches of a reddish colour, and marked with scars where the leaves have fallen off: the leaves are small, oval, waved on their edges, and having several small protuberances on their under side: they sit close to the branches, half embracing them at the base: the flowers are terminating, large, bright, yellow. It is a native of Majorca.

The second species has a stem a cubit and half high, round, smooth, rufescent: the leaves are pale green, paler underneath, an inch long and half an inch wide, roundish, opposite: the flowers terminating: calyx green: corolla pale yellow, five times as large as in the common sort. It is a native of the Pyrenees.

The third has a perennial, thick, woody root, of a reddish colour, sending out very long fibres: the stems suffruticose or under-shrubby, ancipital two-edged or slightly winged on opposite sides, two feet high and more, branched towards

the top, of a reddish colour, and smooth: branches brachiate or decussated, spreading: the leaves opposite, sessile, ovate, entire, smooth, dark green, glaucous on the under side, netted with numerous projecting veins and nerves, which become through age ferruginous: on the stem they are two inches long, and an inch and half broad at the base; those on the branches are smaller, of different sizes, and some of them approaching to lanceolate: the flowers small for the size of the plant, disposed in a cyme: the peduncles round, smooth, usually two- or three-flowered, but sometimes one-flowered: the fruit an ovate capsule, assuming the appearance of a berry; at first yellowish green, then red or brownish purple, and lastly almost black when ripe. It is a native of the south of Europe.

The fourth species rises with a shrubby stalk six or seven feet high, dividing into branches at top: the leaves are oblong, set by pairs close to the branches, having a strong odour, but less than those of the fifth: the flowers terminating in clusters, very like those of the fifth. It is a native of the Canary islands, flowering from July to September.

The fifth rises with shrubby stalks three feet high, sending out small opposite branches at each joint: the leaves are oblong, ovate, placed by pairs, sessile, and having a rank smell: the flowers are in terminating bunches. It is a native of the south of Europe, flowering from July to September.

There are varieties, one larger, which is the common one: the other smaller.

The sixth has a root composed of many woody fibres, striking deep into the ground: the stems several, shrubby, near two feet high, covered with a purplish bark: the leaves stiff, smooth, about two inches long, and a quarter of an inch broad, opposite, sessile, of a lucid green on their upper surface, and gray underneath, having many transverse veins running from the midrib to the border: the flowers terminating in small clusters, each on a short peduncle. It is a native of China, flowering from March to September.

Culture.—The first and last sorts are more tender than the others, requiring the protection of the green-house in winter. They are capable of being increased by layers or cuttings. The former are made in the spring on the young shoots, which, when well rooted in the end of summer, may be taken off and planted out in separate pots. The cuttings of the young shoots may be planted in pots in the summer, and plunged in a hot-bed, and when well rooted, removed into separate pots.

The last species may likewise be increased by planting slips of the roots in the spring, in the same manner.

They may also be raised by sowing the seed in pots, in the spring, and plunging them in a hot-bed just to bring up the plants.

The second and third sorts are readily increased by sowing the seeds in the autumn, in a bed of common earth, or where they are to remain.

They are, however, best raised by slipping the roots, and planting them, at the same time, where the plants are to grow.

The fourth and fifth sorts are easily increased by planting slips from the old roots in the autumn or spring, taken with root fibres to them; or by dividing the roots, and planting them where they are to grow, or in nursery rows.

They may likewise be increased by seeds, sown as in the two former species, removing them in the spring following to where they are to remain.

The two tender sorts afford variety in greenhouse collections, and the other sorts in the borders, clumps, and other parts of pleasure grounds.

HYSSOP. See **HYSSOPUS.**

HYSSOPUS, a genus affording a plant of the low under-shrubby perennial kind.

It belongs to the class and order *Didynamia Gymnospermia*, and ranks in the natural order of *Verticillatæ*.

The characters are: that the calyx is a one-leaved perianthium, cylindrical, oblong, striated, acutely five-toothed, permanent; the corolla one-petalled, ringent: the tube cylindrical, slender, the length of the calyx: throat inclined: upper lip straight, flat, short, roundish, emarginate: lower lip trifid: lateral segments shorter, blunt, the middle one cernate, obcordate, acute, with distant lobes: the stamina have four upright filaments, longer than the corolla, distant; the two upper ones shorter, but the two longer nearer to the lower lip: anthers simple: the pistillum is a four-parted germ: style filiform, under the upper lip, and of the same length: stigma bifid: there is no pericarpium: calyx fostering the seeds: the seeds four, subovate.

The species cultivated is: *H. officinalis*, Common Hyssop.

It has a woody, hard abiding root, the thickness of a finger: the stem very numerous, from a foot to eighteen inches high, shrubby, straight, not much branched; whilst tender square, but becoming round as they grow woody: the leaves numerous, narrow, smooth, entire, like those of Lavender, but much shorter, acute, dotted: whorls of flowers from the bosoms of the leaves, on two, many flowered peduncles, shorter than the leaf, directed one way, and continued into a spike. It is a native of the South of Europe, flowering in July and August.

There are several varieties, blue-flowered, white-flowered, red-flowered, long-spiked, with deep blue flowers, curled-leaved, striped-leaved.

Culture.—This plant may be increased by seed, slips, and cuttings.

The seed should be sown in a bed or border of light earth in the spring, and raked in; and when the plants are come up, thin them if too close, and when about three or four inches high, plant them out where they are to remain. When it is designed to form an edging of them, the seed may be sown at once where the plants are to remain, in small drills, and covered half an inch deep.

In the latter methods, a quantity of the robust side-shoots should be slipped or cut off, planting them in a shady border five or six inches apart; giving water as soon as planted, and repeating it occasionally. They will soon strike root, and in autumn may be planted out where they are to stand.

The common blue-flowered kind is the sort chiefly used, which is generally cultivated, sometimes in close rows, by way of edgings to beds or borders, clipping them annually to keep them regular, and within due compass; and sometimes disposed in beds, &c. in rows fifteen or eighteen inches asunder, and the same distance between the plants in each row. The young leafy shoots and lower-spikes are the parts proper for use, and may be cut any time when wanted. The flower-stalks should be cut down for use in the summer, and tied in bunches.

All the varieties may also be employed to adorn the borders, and other parts of the pleasure-ground, disposing them here and there singly to form bushy plants.

OF

PRACTICAL GARDENING, &c.

J A C

JACA TREE. See **ARTOCARPUS**.

JACK-IN-A-BOX. See **HERNANDIA**.

JACQUINIA, a genus containing plants of the shrubby exotic kind for the stove.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Dumosæ*.

The characters are: that the calyx is a five-leaved perianthium: leaflets roundish, concave, permanent: the corolla is one-petalled: tube bell-shaped, ventricose, longer than the calyx: border ten-cleft: divisions roundish, of which the five interior ones are shorter: the stamina have five awl-shaped filaments, arising from the receptacle: anthers spear-shaped: the pistillum is an ovate germ: style the length of the stamens: stigma headed: the pericarpium is a roundish acuminate berry, one-celled: the seed single, roundish, and cartilaginous.

The species cultivated are: 1. *J. armillaris*, Obtuse-leaved Jacquinia; 2. *J. ruscifolia*, Prickly Jacquinia.

The first is a very elegant upright shrub, seldom more than four or five feet high: the trunk round, thicker, and knobbed where the branches come out, covered with an ash-coloured bark: the branches four or five from each joint towards the top, in whorls, spreading, stiff, round, grooved, brittle, hoary, subdivided, and forming altogether a neat globular head: the leaves scattered, alternate, petioled, clustered towards the ends of the twigs, wedge-shaped, ovate, obtusely margined, quite entire, veinless, smooth, pale underneath, with very minute black dots:

VOL. II.

J A C

the racemes terminating, commonly shorter than the leaves, about two inches long, solitary, erect, loose, simple, seven-flowered, or thereabouts: the peduncles scattered, spreading, one-flowered: the flowers small, stiffish, white, smelling like Jasmine, and retaining their sweet scent several days. It is a native of South America, flowering in February and March.

The second species is a shrub three feet in height, having the habits of the first; but it differs in the leaves being lanceolate, acuminate, pungent, extremely stiff, and one-flowered. It is a native of South America, flowering in January and February.

Culture.—These plants are capable of being increased by sowing the seeds, procured from their native situation, in pots of light earth, in the spring season, plunging them in a bark hot-bed. When they have attained a few inches in growth, they must be removed into separate pots, and be replunged in a hot-bed in the stove, where they must be constantly kept.

They may likewise be raised by planting cuttings of the young shoots, in pots of the same sort of earth, in the early spring, plunging them in the bark hot-bed, as in the other case; but in this way they are raised with difficulty.

They afterwards require to be carefully managed, by having little water given in the winter time, but a free admission of air during the hot summer season, and occasional refreshings of water.

They afford variety in stove collections.

B

JASMINUM, a genus containing plants of the hardy and tender deciduous and evergreen shrubby kinds.

It belongs to the class and order *Diandria Monogynia*, and ranks in the natural order of *Sepiaria*.

The characters are: that the calyx is a one-leaved perianthium, tubulated, oblong: mouth five-toothed, upright, permanent: the corolla one-petalled, salver-shaped: tube cylindric, long: border five-parted, flat: the stamina have two short filaments: anthers small, within the tube of the corolla: the pistillum is a roundish germ: style filiform, length of the stamens: stigma bifid: the pericarpium is an oval berry, smooth, two-celled, or two-capsuled: the seeds two, large, ovate-oblong, arillated, convex on one side, flat on the other.

The species cultivated are: 1. *J. officinale*, Common White Jasmine; 2. *J. fruticans*, Common Yellow Jasmine; 3. *J. humile*, Italian Yellow Jasmine; 4. *J. odoratissimum*, Yellow Indian Jasmine; 5. *J. grandiflorum*, Spanish, or Catalonian Jasmine; 6. *J. Sambac*, Arabian Jasmine; 7. *J. Azoricum*, Azorian Jasmine.

The first has a shrubby, weak, climbing, round, smooth, branching stem: the leaflets usually seven, broad, lanceolate, quite entire, smooth, dark green, the end one larger and more pointed than the rest: the peduncles few-flowered: the calycine segments capillary: the corolla white and odorous: the flowers appear most part of summer. Its native country is not well ascertained; probably the East Indies.

It varies with white striped leaves, and with yellow striped leaves.

The second species has weak angular branches which require support, and rise to the height of eight or ten feet, if planted against a wall or pale: the leaves are trifoliate, simple, alternate: the flowers are yellow, coming from the sides and ends of the young branches. It is a native of the south of Europe. It sends out numerous suckers from the roots.

The third has shrubby firm stalks and angular branches, of low strong growth, and bushy: the flowers are generally larger than those of the preceding, but have very little scent, and are seldom produced so early in the season: the simple leaves are frequently intermixt with the ternate ones. Its native country is not known; but it flowers from July to September.

The fourth species rises with an upright woody stalk eight or ten feet high, covered with a brown bark, sending out several branches, which want no support: the leaflets are of a lucid green, ovate and entire, continuing green all the year, the two side ones much less than the

end one: the flowers are produced at the ends of the shoots in bunches, of a bright yellow colour, and a most grateful odour. It is a native of the island of Madeira, flowering from July to October and November, which are frequently succeeded by oblong oval berries.

The fifth has much stronger branches than the first sort: the leaflets are placed closer, and are of a lighter green; the side ones are obtuse, but the odd one ends in an acute point: the flowers are axillary, on peduncles two inches long, each sustaining three or four flowers, of a bluish red on their outside, but white within. It is a native of the East Indies, flowering from July to November.

The sixth species rises with a winding stalk to the height of fifteen or twenty feet, sending out many small branches: the leaves are smooth, near three inches long, and almost two broad, of a light green, on short foot-stalks, ending in acute points: the flowers are produced at the end of the branches, and also upon the side shoots, on short peduncles, each generally sustaining three flowers, the two lower opposite, and the middle one longer: these flowers are of a pure white, and have a most agreeable odour, somewhat like orange flowers, but sweeter; when fully blown they drop out of their cups upon being shaken, and frequently fall out in the night, changing soon to a purplish colour: the plants continue flowering great part of the year, when they are kept in a proper temperature of warmth. It is a native of the East Indies.

There are varieties of it with single and double flowers, and with large double flowers.

The seventh has longer slender branches, which require support, and may be trained twenty feet high: the leaves are of a lucid green, continuing all the year: the flowers terminating, in loose bunches, of a white colour, and very agreeable scent. It is a native of the Azores, flowering from May to November.

Culture.—The first sort is readily increased by layers or cuttings. The young branches should be laid down in the early autumn, and in the following autumn be taken off, and planted where they are to grow. The cuttings of the young shoots may be planted either at the same time or in the early spring, being protected in the first case, in severe weather, in the winter. When they are well rooted, they may be removed, with balls of earth about their roots, to the places where they are to grow.

The different varieties are increased by budding, or grafting them upon stocks of the plain or common kind. See **Budding** and **Grafting**.

The common sort must be planted against walls, pales, or other fences, that may serve as a support. When planted as a standard, it is difficult to train to a proper head, and keep in order, without destroying the flowering branches which are the extremities of the same year's shoots. On this account they should be permitted to take their natural growth in the summer, and not pruned or nailed till towards the latter end of March, when the frosts are over, to prevent their being injured by them.

The varieties should be planted in a warmer situation, with a southern aspect, than the common sort, especially the first, which, in very severe winters, should be protected with mats.

The second sort may be increased by layers, or planting the suckers taken from the roots, in the spring or autumn. The layers may be made as in the first sort.

The third sort is capable of being propagated either by budding or inarch-grafting upon stocks of the second kind, or by layers of the young tender branches made in the autumn or early spring seasons; but the former is the better practice, as producing more hardy plants. It should have a rather warm aspect, as a south wall, and, in very severe winters, have the protection of mats.

It requires the same pruning as the first sort.

The four following sorts are more tender.

The first of them may be increased by seeds or layers of the young shoots. The seeds should be sown in the early spring, in pots of fresh light earth, plunging them in a moderate hot-bed, and when the plants are up, removing them into a second hot-bed to forward them, giving them frequent slight refreshings of water, and gradually hardening them to the full air. They should be occasionally watered in the winter, and in the spring following be removed into separate pots, the earth being carefully preserved about their roots. Their first growth may be promoted by placing them in a mild hot-bed. They afterwards require a pretty free air, and slight protection from frosts in winter. They should have the decayed branches pruned out in the spring, without the others being shortened, as the flowers are produced at the extremities of the branches.

In the layer method the young shoots should be laid down in the early spring, as about March, being slightly nicked underneath at a joint, and often slightly watered in dry weather. In the following spring they may be taken off, and planted out in pots filled with light earth, separately; being afterwards managed as the others.

They may likewise be raised by inarch-grafting into stocks of the second species; but the plants produced in this way are not so strong as those upon their own stocks, and they are apt to send out too many suckers from the roots.

The second of these tender kinds may be raised by budding or inarch-grafting upon stocks of the first species, which renders it more hardy than on its own; but the plants are mostly brought from Italy, in bunches of four together, and which, after having their roots moistened, and the shoots and dead parts pruned away, as well as the tops cut down to within a few inches of the grafted parts, may be planted in pots filled with light fresh earth, plunging them in a moderate bark hot-bed, shading them from the sun, and giving them water. When they begin to grow, all the shoots below the grafts should be rubbed off, and the top shoots cut off, free air being admitted, so as to gradually harden them to be set out in a warm situation. They must have the protection of the green-house in winter, and be frequently sparingly watered, a free air being admitted in mild weather.

The third of these tender sorts may be raised by layers and cuttings; but the first is the best method, as the cuttings require much care to make them strike. The young branches should be laid down in the spring, in pots filled with soft loamy earth, plunging them in a tan hot-bed, and watering them occasionally. In the autumn, when they have stricken root, they should be taken off, and planted out in separate small pots, plunging them in a hot-bed, due shade being given. The cuttings may be planted in pots of the same sort of earth during the summer, plunging them in a tan hot-bed, and covering them close with a bell or hand glass, due shade being given, and occasional waterings. When they have taken good root, in the beginning of autumn, they may be removed into separate pots, and be managed as those from layers.

These plants succeed best when kept in the stove.

The last of these sorts may be increased in the same way as the fourth species, and requires the same management afterwards.

The three first species may be employed as plants of ornament for covering walls, palings, and other naked erections about houses, as well as occasionally introduced as standards in clumps, borders, and other parts of pleasure-grounds.

The other sorts afford variety among other potted green-house and stove plants. Some may likewise be trained against warm walls or palings, especially the last kind, which has a fine fragrance.

JATROPHA, a genus containing plants of the flowering shrubby perennial kind.

It belongs to the class and order *Monocotyledonae*, and ranks in the natural order of *Tricoccæ*.

The characters are: that in the male flowers the calyx is a scarcely manifest perianthium: the corolla one-petalled, funnel-form: tube very short: border five-parted: divisions roundish, spreading, convex, concave beneath: the stamens have ten awl-shaped filaments, approximated in the middle: the five alternate ones shorter, upright, shorter than the corolla: anthers roundish, versatile: the pistillum is a weak rudiment, latent in the bottom of the flower: female flowers in the same umbel with the males: calyx none: the corolla five-petalled, rosaceous: the pistillum is a roundish, three-furrowed germ: styles three, bifid: stigmas simple: the pericarpium is a roundish capsule, tricocous, three-celled, cells bivalve: the seeds solitary and roundish.

The species cultivated are: 1. *J. gossypifolia*, Cotton-leaved Physic-nut, or Wild Cassava; 2. *J. multifida*, French Physic-nut; 3. *J. manihot*, Eatable-rooted Physic-nut, or Cassava; 4. *J. wreni*, Stinging Physic-nut.

The first has the stem from two to three feet high, herbaceous, branched, smooth: the branches subdivided, round, beset at the base with branched glanduliferous cilia or bristles: the leaves are digitate, veined, tender, often three-lobed: lobes acute, serrate, toothed and ciliate; cilia glandular: the common peduncle terminating: partial cymed, bifid: male flowers very copious, females solitary, in the forks of the peduncles: in the males, calyx five-leaved: leaflets ovate, acute, ciliate: corolla deeply five-parted, dark purple: segments ovate: at the base of the stamens are five roundish nectareous glands. It is a native of the West Indian islands.

The second species grows generally to the height of five, six, or seven feet, with a very smooth suffrutescent stem, and spreading branches: the stipules bristle-shaped, multifid at the base of the branches and petioles: the leaves alternate, subpeltate, multifid: the divisions pinnate, with the odd leaflet longer, smooth, but whitish underneath: the peduncles terminating, very long, round, thick, very smooth, subdivided: the pedicels coloured, in corymbs: the flowers small, red: males very numerous: females solitary, subsessile. It is common in most of the islands in the West Indies, flowering from June to July.

The third shoots from a tough, branched, woody root, whose slender collateral fibres

swell into those fleshy conic masses for which the plant is cultivated; and rises by a slender woody knotted stalk to the height of four, five, or six feet, sometimes more: the leaves alternate, smooth, on long petioles, seven-lobed: lobes narrow at the base, growing broader till within an inch and half of the top, where they diminish to an acute point: the three middle lobes are about six inches long, and two broad where broadest; the two next are about an inch shorter, and the two outside lobes are not more than three inches long; the middle lobes are sinuated on each side near the top, but the two outer are entire: the flowers are produced in umbels at the top of the stalks, some male, and others female. It is a native of South America.

It is observed by Martyn, that "it grows to perfection in about eight months; but the roots will remain a considerable time in the ground uninjured. They are generally dug up as occasion requires, and prepared for use in the following manner: being first well washed and scraped, then rubbed to a pulpy farina on iron graters, they are put into strong linen or palm-etto bags, and placed in a convenient press, until the juice is entirely expressed: the farina is then taken out and spread in the sun for some time, pounded in large wooden mortars, run through coarse sieves, and afterwards baked on convenient irons. These are placed over proper fires, and, when hot, bestrewed with the sifted meal to whatever size or thickness people please to have the cakes made: this agglutinates as it heats, grows gradually harder, and, when thoroughly baked, is a wholesome well-tasted bread. *Tapioca* is also prepared from this root."

The fourth species has a thick, swelling, fleshy root, from which arises an herbaceous stalk as big as a man's thumb, four or five feet high, and dividing into several branches; these are very closely armed with long brown spines: the foot-stalks of the leaves are six or seven inches long, which are also armed with spines, but not so closely, nor are the spines so long as those on the stalk and branches: the leaves are deeply cut into five lobes, which are jagged deeply on their sides, and the nerves are armed with stinging spines: the flowers are produced in umbels at the top of the branches, standing upon long naked peduncles; they are of a pure white colour: the male flowers appear first; they are five-petalled, forming a short tube at bottom, and spreading open flat above. It is a native of Brazil, flowering from May to July.

Culture.—These plants are all capable of being increased by seeds and cuttings.

The seeds should be sown in the early spring, in pots of light earth, plunging them in a mild hot-bed of bark. When they have attained a little growth, the plants should be pricked out into separate small pots, and be replunged in the hot-bed, a little water being given.

The cuttings should be made from the stalks or young branches five or six inches in length, and planted in pots of light earth in the spring or summer months, plunging them in the bark hot-bed. When they have stricken good root they should be removed with earth about their roots into separate pots, and be replunged in the hot-bed, being duly watered and shaded.

The third sort, or the Cassava, according to Martyn, "thrives best in the West Indies, in a free mixed soil where it is propagated by the bud or gem, in the following manner: The ground is first cleared, and hoed up into shallow holes, of about ten or twelve inches square, and seldom above three or four inches in depth. When they intend to plant, they provide a sufficient number of full-grown stems, and cut them into joints, of about six or seven inches length, as far as they find them tough and woody, and well furnished with prominent, well-grown, hardy buds: of these they lay one or two in every hole, and cover them over with mould from the adjoining bank; but care must be taken to keep the ground clean, until the plants rise to a sufficient height to cover the mould, and to prevent the growth of all weaker weeds."

This root, though of a poisonous quality, serves for bread to the inhabitants of the West Indies, when divested of this property, which is done by rubbing the root forcibly upon a strong copper grater, till reduced to a rough saw-dust-like powder, or meal: it is then put into a press to squeeze out the poisonous juice; and, being sufficiently pressed and sifted, is made into bread, by spreading it two or three inches thick, upon an iron plate heated over the fire; and thus the parts join, incorporate, and become cake bread, which is accounted very nourishing.

They all require to be sparingly watered in the winter season, to prevent their rotting; and to be kept constantly in the stove, where they afford variety, and a fine appearance in their large foliage and flowers.

IBERIS, a genus containing plants of the herbaceous, annual, perennial, and under-shrubby kinds.

It belongs to the class and order *Tetradynamia Siliculosa*, and ranks in the natural order of *Siliculosæ*, or *Cruciformes*.

The characters are: that the calyx is a four-

leaved perianthium: leaflets obovate, concave, spreading, small, equal, deciduous: the corolla is four-petalled, unequal: petals obovate, obtuse, spreading: claws oblong, upright: of these the two exterior petals are far larger, and equal to each other: the two interior very small, reflex: the stamina have six awl-shaped filaments, upright: of which the two lateral ones are shorter: anthers roundish: the pistillum is a roundish, compressed germ: style simple, short: stigma obtuse: the pericarpium is an upright, suborbiculate, compressed silicle, emarginate, surrounded by a sharp edge, two-celled: partition lanceolate: valves navicular, compressed, carinated: the seeds a few, and subovate.

The species are: 1. *I. umbellata*, Purple Candy-tuft; 2. *I. amara*, White Candy-tuft; 3. *I. linifolia*, Flax-leaved Candy-tuft; 4. *I. odorata*, Sweet-scented Candy-tuft; 5. *I. rotundifolia*, Round-leaved Candy-tuft; 6. *I. semperflorens*, Broad-leaved Evergreen Candy-tuft; 7. *I. sempervirens*, Narrow-leaved Evergreen Candy-tuft; 8. *I. Gibraltarica*, Gibraltar Candy-tuft.

The first has an annual root, white, oblong, fusiform: the stem upright, leafy, half a foot, or from a span to a foot in height, subangular, green, smooth, branching: the leaves are frequent, alternate, lanceolate, acuminate, smooth: the flowers in a hemispherical corymb, on peduncles half an inch in length, of a pale purple colour. It is a native of the south of Europe, flowering in June and July.

There are varieties with bright purple flowers, and with white flowers.

The second species resembles the first very much, but is smaller: the stem is seven or eight inches high, pubescent, somewhat rugged, branched: branches diffused, alternate, the lower ones sometimes opposite, not rising all to the same height: the leaves are alternate, oblanceolate, or linear-lanceolate, blunt, sessile, decurrent, bright green, thickish, smooth, the lower ones serrate, the rest toothletted, especially in front, or with a tooth or two on each side: the flowers white, in a terminating spike-like raceme; or rather, in a corymb lengthened into a raceme as the inflorescence advances. It is a native of Switzerland, &c.

The third has a simple, white, twisted root, having few fibres: the root-leaves lanceolate-linear, serrate, withering and falling as the stem advances: stem-leaves linear, quite entire, sessile, few, gradually shorter, sharpish: the stem herbaceous, straight, slender, branched at top: branches mostly bifid: the flowers of a purple colour, in corymbs, the outer ones peduncled,

with the two other petals larger. It is a native of Spain, &c. and is annual, flowering in July.

The fourth species seldom grows so large as the first, and the flowers are much smaller, but have an agreeable odour. They are in close corymbs and are of a snowy whiteness. It is a native of Geneva.

The fifth has a creeping stem; the leaves are smooth, soft; those next the root quite entire and petioled, those on the stem smooth and entire: the flowers are reddish purple, almost regular, in racemes, on spreading peduncles. It is a native of Switzerland, flowering from May to July.

The sixth species is a low shrubby plant, which seldom rises above a foot and half high, having many slender branches, which spread on every side, and fall towards the ground if they are not supported. These branches are well furnished towards their extremity with leaves, which continue green all the year; and in summer the flowers are produced at the end of the shoots, are white, and grow in an umbel, continue long in beauty, and, being succeeded by others, the plants are rarely destitute of them from the end of August to the beginning of June. It is a native of Persia, &c.

There is a variety with white striped leaves.

The seventh is of humbler growth than the sixth, seldom rising more than six or eight inches high, the branches rather herbaceous: the leaves continue green through the year, and the flowers are of as long duration as those of the sixth species. It is a native of the Island of Candia, flowering from April to June.

In the eighth species the stems are many, thick, green, striated, ascending from a foot to eighteen inches in length, divided into several branches: the leaves alternate, gradually widening from a narrow base, ending in a blunt point, thick, smooth, veinless except in the middle, dark green above, somewhat paler underneath: the flowers terminating in corymbs, at first white, afterwards pale purple, without scent. It is a native of Spain, flowering early in the spring.

The stems are ridged and woody, and the leaves larger and less bluntly toothed in the cultivated plant. The flowers are also twice as large.

Culture.—The four first annual sorts must be raised annually from seed, by sowing it at different times in the spring, in patches, in the fronts of borders, clumps, and other parts of pleasure-grounds, where the plants are to flower, thinning them properly afterwards.

The fifth sort may be raised by planting the root off-sets and cuttings as below.

The three shrubby perennial sorts may be increased by slips and cuttings, which should be planted out in pots, plunging them in a moderate hot-bed, or in a warm shaded border in the later spring and early summer months, water being occasionally given. When well rooted in the autumn, they should be removed into pots, being protected in the winter season in the green-house.

The first sorts are very ornamental in the open ground, when properly varied. And the latter in green-house, and other potted collections. A few of them may likewise be set out in the warm shrubby borders.

IBISCUS. See **HIBISCUS**.

ICACO. See **CHRYSORALANUS**.

ICE-HOUSE, a sort of building sunk in the ground for the purpose of preserving Ice in for use in the summer season.

The proper situation for an Ice-House, is that of a dry spot of ground; as wherever there is moisture, the Ice will be liable to dissolve: of course in all strong soils, which retain the wet, too much care cannot be taken to make drains all round the houses to carry off moisture; as when this is lodged near them, it will occasion a damp, which is always prejudicial to the keeping of Ice.

The places should likewise be elevated, that there may be descent enough to convey off any wet that may happen near them, or from the Ice melting; and also, as much exposed to the sun and air as possible; not under the drip, or in the shade of trees, as is too often the practice, under the supposition, that if exposed to the sun, the Ice will melt away in summer, which never can be the case where there is sufficient care taken to exclude the external air, as the heat of the sun can never penetrate through the double arches of the buildings, so as to add any warmth to the internal air; while, when entirely open to the sun and wind, all damps and vapours are readily removed.

The form of the building may be according to the fancy of the owner; but for the well into which the Ice is put, a circular form is the most convenient; the depth and diameter of it being proportioned to the quantity of Ice wanted; but it is always best to have sufficient room, as when the house is well built, it will keep the Ice two or three years: and there will be this advantage in having it large enough to contain Ice for two years consumption, that, if a mild winter should happen, when there is not Ice to be had, there will be a stock to supply the want in the House.

Where the quantity wanted is not great, a well of six feet diameter, and eight feet deep, will be large enough; but for a large consump-

tion, it should not be less than nine or ten feet diameter, and as many deep: where the situation is either of a dry chalky, gravelly, or sandy kind, the pit may be made entirely below the surface of the ground; but in strong loamy, clayey, or moist ground, it will be better to raise it so high above the surface, as that there may be no danger from the wetness of the soil.

At the bottom of the well there should be a space about two feet deep left, for receiving any moisture which may drain from the Ice, and a small underground drain should be laid from this, to carry off the wet; over this space should be placed a strong grate of wood, to let the moisture fall down, which may at any time happen, from the melting of the Ice. The sides of the well must be walled up with brick or stone at least two feet thick; but if it be thicker it will be better, as the thicker the walls are made, the less danger there is of the well being affected by external causes. When the wall of the well is brought within three feet of the surface, there must be another outer arch or wall begun, which must be carried up to the height of the top of the intended arch of the well; and if there be a second arch turned over from this, it will add to the goodness of the House; but this must depend on the person who builds going to the expense. When not, the plate into which the roof is to be framed must be laid on this outer wall, which should be carried high enough above the inner arch to admit of a door-way in, to get out the ice. Where the building is to be covered with slate or tiles, there should be a thickness of reeds, straw, or other similar material laid under, to guard against the effects of the sun and external air; where they are laid two feet thick, and plastered over with lime and hair, there will be no danger of the heat penetrating.

The external wall of the house need not be built circular, but of any other form, as square, hexangular, or octangular; and where it stands much in sight, may be so contrived as to make it a pleasing object.

Ice-Houses may be built in such a manner as to have alcove seats in the front, having passages to get out and put in the Ice behind them; or the entrance may be behind, to the north; small passages being left next the seats, through which to enter to take out the Ice, a large door being contrived with a porch wide enough for a small cart to back in, to shoot down the ice upon the floor near the mouth of the well, where it may be well broken before it is put down. The aperture of this mouth of the well need not be more than two feet and a half in diameter, which will be large enough to put down the ice, a stone being left to stop it, which must be closed up as securely as possible after the ice is put in,

and all the vacant space above and between this and the outer door be filled close with barley straw, or other similar material, to exclude the external air.

The door to enter for taking out the ice should be no larger than is absolutely necessary for the coming at the ice, and must be strong and close to exclude the air; and at five or six feet distance from this another door should be contrived, which should be closely shut before the inner door is opened, whenever the ice is taken out of the House.

When the House is thus finished, it should have time to dry before the Ice is put into it; as when the walls are green, the damp of them frequently dissolves the Ice. And, at the bottom of the well, upon the wooden grate, some small faggots should be laid; and if upon these a layer of reeds be placed smooth for the Ice to rest upon, it will be better than straw, which is commonly used. In the choice of the Ice, the thinner it is the better it may be broken to powder; as the smaller it is broken the better it will unite when put into the well. In putting it in, it should be rammed close, and a space left between it and the wall of the well, by straw being placed for the purpose, so as to give passage to any moisture that may be collected by the dissolving of the Ice on the top or other-ways.

In putting the Ice into the House, some mix a little nitre with it, to make it congeal more fully; but this is not necessary.

As the Ice becomes solid in the well, an iron crow is necessary to take it up with.

The Ice-House is, as has been seen, capable of being made an ornamental building; but this is seldom done; it being generally placed in a sequestered spot, on the side of a hill or sloping ground, the base of which is lower than the bottom of the well; the outside being well banked up with earth, to keep out all external air and heat, and neatly covered with turf.

In the annexed plate is the plan of an improved Ice-House.

Fig. 1. is a section in the direction of the entrance passage.

- A. Upper covering of earth.
- B. and K. Strata of clay.
- C. Wall of the arched roof of passage.
- D. Entrance passage.
- E. Entrance aperture of the well.
- F. Well.
- G. Side-walls of well, and the cavities of it for the retention of the warm air, which would otherwise make its way to the well.
- H. Pipe for carrying off the water or moisture.
- I. Drain of it.
- L. Door of passage.

Fig. 3. Ground plan of the well.

Fig. 4. Front elevation of the entrance.

N. B. In figures 2, 3, and 4, the letters of reference are placed to the same parts of the building respectively, as in fig. 1.

ICE-PLANT. See MESEMBRYANTHEMUM.

JERUSALEM ARTICHOKE. See HELIANTHUS.

JERUSALEM SAGE. See PHLOMIS.

ILEX, a genus containing plants of the hardy evergreen tree or shrubby kinds.

It belongs to the class and order *Tetrandria Tetragynia* (*Polygamia Dioecia*), and ranks in the natural order of *Dumosæ*.

The characters are: that the calyx is a four-toothed perianthium, very small, and permanent: the corolla one-petalled, four-parted, wheel-shaped: divisions roundish, spreading, rather large, with cohering claws: the stamina have four awl-shaped filaments, shorter than the corolla: anthers small: the pistillum is a roundish germ: style none: stigmas four, obtuse: the pericarpium is a roundish berry, four-celled: the seed solitary, bony, oblong, obtuse, gibbose on one side, cornered on the other.

The species cultivated are: 1. *I. aquifolium*, Common Holly; 2. *I. Cassine*, Dahoon Holly; 3. *I. vomitoria*, South-sea Tea, or Evergreen Cassine.

The first rises from twenty to thirty feet, and sometimes more; but its ordinary height is not above twenty-five feet. The trunk is covered with a grayish smooth bark, and those trees which are not lopped or browzed by cattle, are commonly furnished with branches the greatest part of their length, and form a sort of cone: the leaves are petioled, about three inches long, and one and a half broad, of a lucid green on their upper surface, and pale on their under, having a strong midrib; the edges are indented and waved, with sharp stiff thorns terminating each of the points, some raised upwards, others bent downwards, being fixed into a strong woody border, which surrounds the leaf. When this tree grows naturally, it has flat, entire leaves, without thorns, only ending in a sharp point, mixed with the others, especially as it advances in age: the flowers in clusters from the base of the petioles (from a sort of scale upon the branch) on very short peduncles, each sustaining five, six, or more flowers (generally three together), appearing in May. They are succeeded by roundish berries (crowned with the calyx, which turns black), turning to a beautiful scarlet about Michaelmas, and continuing the greatest part of the winter.

There are a great many varieties of both the

green-leaved and variegated sorts. Of the first the Common Green-leaved Prickly, the Smooth Green-leaved, the Narrow Serrated Green-leaved, the Green-leaved Yellow-berried, the Box-leaved Green, the Hedgehog Green; and of the latter, the Common Prickly, with Silver-striped Leaves, with Gold-striped Leaves, with Blotched Leaves, the Smooth with White-striped Leaves, with Yellow-striped Leaves, with Blotched Leaves, with Narrow-striped Leaves, the Blotched Yellow berried, the Cream-coloured, the Copper-coloured, the White-leaved, the Mottled-edged, the Hedgehog Silver-edged, the Gold-edged Hedgehog, the White Blotched Hedgehog, the Yellow Blotched Hedgehog, the Painted Lady variegated.

The second species rises with an upright branching stem to the height of eighteen or twenty feet; the bark of the old stems is of a brown colour, but that of the younger stems or branches green and smooth: the leaves more than four inches long, and one and a quarter broad in the broadest part, of a light green and thick consistence; the upper part is serrate, each serrature ending in a small sharp spine; they stand alternately on every side of the branches, on very short foot-stalks: the flowers come out in thick clusters from the side of the stalks; they are white, and shaped like those of the first, but smaller. Both the female and hermaphrodite flowers are succeeded by small roundish berries, making a fine appearance in winter; but they have not yet produced fruit in this climate. It is a native of Florida and Carolina.

There are varieties, as with broad leaves, and with narrow leaves, with scarcely any serratures.

The third rises to the height of ten or twelve feet, sending out branches from the ground upwards, which form themselves into a sort of pyramid: the leaves are about the size, shape, texture, and colour of the small-leaved alaternus, but somewhat shorter, and a little broader at the base: the flowers are produced in close whorls at the joints of the branches, near the foot-stalks of the leaves: they are white, and are succeeded by bright red berries, which continue upon the plants most part of the winter, and make a fine appearance, intermixed with the green leaves. It is a native of West Florida.

Culture.—These plants are all capable of being increased from seeds, and by the operations of budding and grafting.

The seeds or berries should be sown as soon as they are perfectly ripened, in small beds prepared for the purpose. But as they are long in germinating, it is the practice with some to deposit them for a year before they are sown in

the beds, in pots filled with earth or sand, or in a hole in the earth, in a dry situation; the first is probably the best method.

The plants mostly rise in the second spring, when they should be kept well weeded and watered.

After they have had two years' growth in these beds, they should be removed, and planted out in nursery rows at the distance of two feet, and one apart in the rows. They should remain in these till of proper size to be planted where they are to remain, keeping them perfectly clean, and the ground occasionally stirred about them.

The proper seasons for removing them are either the early autumn or spring; the former in dry grounds, and the latter in those that are of a retentive nature.

In the second sort the seeds, after being prepared as above, should be sown in pots, and plunged the second spring in a gentle hot-bed, in order to bring up the plants. They should then be kept in the pots, and have protection in the winter season till they have become of hardy growth, when they may be turned out, and planted in warm situations. They afterwards require protection in very severe winters.

The third sort may be managed in the same way as the second, the young plants being gradually inured to the open air, having only the morning sun at first. They should be kept in the pots four or five years, as they grow slowly, being well protected in the winter. They all succeed best in a dry soil.

All the varieties of the different sorts are to be continued either by budding or grafting upon stocks of the first sort. The first should be performed in the latter part of the summer, and the latter in the early spring, upon stocks of two years' growth. See BUDDING and GRAFTING.

All the sorts and varieties are highly ornamental in the clumps, borders, and other parts of pleasure-grounds, affording much variety when judiciously intermixed. The first sort frequently rises to a large tree, having a fine white hard wood, useful for various purposes. The bark also affords the substance called *bird-lime*, which is prepared by boiling it till the green part is capable of being separated from the white, then laying it in a cool cellar for a few days, afterwards pounding it till it becomes a tough paste, washing it repeatedly, till it becomes quite clear, then placing it in an earthen vessel to ferment or become fine, when it will be fit for use.

ILLECEBRUM, a genus containing plants of the herbaceous, flowery, biennial, and shrubby perennial kinds.

VOL. II.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Holoraceæ*.

The characters are: that the calyx is a five-leaved cartilaginous perianthium, five-cornered, with coloured leaflets, which are sharp, with distant points, permanent: there is no corolla: the stamina have five capillary filaments, within the calyx: anthers simple: the pistillum is an ovate germ, sharp, ending in a short bifid style: stigma simple, obtuse: the pericarpium is a roundish acuminate capsule, both ways five-valved, one-celled, covered by the calyx: the seed single, roundish, sharp on both sides, very large.

The species cultivated are: 1. *I. lanatum*, Woolly Illecebrum; 2. *I. suffruticosum*, Shrubby Illecebrum, or Knot-grass; 3. *I. Paronychia*, Mountain Illecebrum, or Knot-grass.

The first has a rigid round stem, somewhat hairy, branched only at the base: the leaves are lanceolate, ovate, subsessile, opposite, petioled, quite entire, sharpish, naked, pubescent underneath: (spikes close, oblong, and axillary:) the peduncles lateral, very short, in three or four sessile spikes, unequal to the leaflet: stamens connected at the base by means of a five-toothed crown: the seed kidney-form. It is a native of the East Indies, biennial, and flowering most part of the year.

It varies in size. This is the smaller one. The Great Woolly Illecebrum has solitary, not aggregate spikes. And, according to Retzius, there is a remarkable variety with round leaves, in Malabar.

The second species has woody stems about a foot high, with small leaves like those of Knot-grass: the flowers come out singly on the side of the stems, and make no great appearance. It is a native of the south of Europe, flowering from May to August.

The third has trailing stalks near two feet long, with leaves like those of the second kind; the heads of flowers come out from the joints of the stalk, having neat silvery bractes surrounding them, which make a pretty appearance: the flowers appear in June, and there is generally a succession of them for at least two months. It is perennial, and a native of the south of Europe.

Culture.—The first sort may be increased by sowing the seeds in pots of light mould, in the spring, in the same manner as the amaranthus, plunging them in a mild hot-bed. And if they be afterwards plunged in the tan-bed in the stove, these branches will often put out roots by which they may be raised.

Cuttings of the branches managed in the same way will sometimes grow.

C

The two last sorts may be propagated by seeds and cuttings.

The former should be sown in the spring, as about April, in pots, or on a bed of light earth. When the plants have attained some growth, they should be taken up carefully with earth about their roots, and placed, some in pots, and the others in a dry warm border, due water and shade being given; those in pots being protected by a frame and glasses in the winter, and those in the open ground screened in severe frosts, by mats or other means, and kept perfectly clean.

They may also be increased by planting cuttings of the branches, in the summer months, as about June, in pots or a shady border. When they have taken good root, they may be removed to the places where they are to grow, or into other pots, moist weather being chosen for the purpose.

The first sort affords variety in the stove or green-house collections; and the latter in the borders, and among potted plants of the more hardy kinds.

IMMORTAL FLOWER. See **GNAPHALIUM.**

IMPATIENS, a genus containing plants of the flowery annual kind.

It belongs to the class and order *Syngenesia Monogamia*, and ranks in the natural order of *Corydales*.

The characters are: that the calyx is a two-leaved perianthium, very small: leaflets roundish-acuminate, equal, placed towards the sides of the flower, coloured, deciduous: the corolla is five-petalled, ringent: petals unequal; of which the superior is roundish, flat, upright, slightly trifid, constituting the upper lip: lower pair reflex, very large, outwardly larger, obtuse, irregular, constituting the lower lip: intermediate pair opposite, rising from the base of the upper petal: nectary one-leaved, receiving in the manner of a hood the base of the flower, oblique at the mouth, rising outwardly, ending in a horn at the base: the stamina have five filaments, very short, narrower towards the base, incurved: anthers as many, connate, divided at the base: the pistillum is a superior germ, ovate-acuminate: style none: stigma simple, shorter than the anthers: the pericarpium is a one-celled capsule, five-valved, springing open elastically, the valves rolling spirally: the seeds several, roundish, fixed to a columnar receptacle.

The species cultivated are: 1. *I. Balsamina*, Garden Balsam; 2. *I. Noli me tangere*, Common Yellow Balsam.

The first is an annual plant, rising a foot and half high, and dividing into many succulent branches: the leaves long and serrate: the flowers come out from the joints of the stem,

upon slender peduncles about an inch long, each sustaining a single flower; but there are two, three, or four of these peduncles arising from the same joint: the flowers red or white. It is much increased in size by cultivation; and is a native of the East Indies, &c.

There are varieties with single and double red flowers, with single and double scarlet flowers, with single and double white flowers, with single and double purple flowers, with variegated single and double flowers, with large double variegated scarlet and white flowers, with large double variegated purple and white flowers, with double red and purple flowers, and with large double bizarre flowers.

The second species has an annual root: the stem a foot high, upright: stem and branches pale yellowish green, smooth and shining, somewhat transparent, thickest at the joints, succulent and brittle: the branches sometimes opposite: the lower leaves ovate, uppermost elliptical or lanceolate, irregularly serrate, all smooth, petioled: the upper part of the stem flexuose, forming an obtuse angle opposite to each leaf: some of the branchings of the peduncles have bractes, and some not: the flowers yellow; the lateral petals spotted with red, by cultivation changing to pale yellow or purplish; these are blunt, slightly two-lobed, with an oval appendix at the base, about an inch in length, and above half an inch in breadth. It is a native of Europe.

When the seeds are ripe, upon touching the capsule they are thrown out with force; hence the name.

Culture.—These beautiful plants are all capable of being increased by sowing the well-ripened seeds of the best varieties annually, in the spring, in the first sort, in pots filled with light, dry, good earth, or in the mould of the bed, plunging them in the former case in the hot-bed; or in the natural ground, in the borders, in a warm dry situation, covering them with glasses; but the two former are the best methods. When the plants are up, they must have air admitted freely every day when fine, and occasional moderate waterings. After they have attained a few inches in growth, they should be carefully removed into separate pots, with balls of earth to their roots, being replunged in the hot-bed, or be pricked out on a fresh hot-bed. Those in the natural ground should be kept properly thinned, and be removed into pots, or the situations where they are to flower, about the end of June, with balls of earth, as in the others.

It is a practice with some to remove those in pots and on hot-beds a second time in about a

month; but they grow stronger where this is avoided, by placing them at first in larger pots, and thinner in the bed, so as to have full room to rise to a proper size. The frames should be raised as the plants advance in growth.

About the beginning of June they should be gradually exposed to the influence of the full air, in order to harden them, that they may be set out towards the end of it; when they should have sticks placed for their support, to which they should be neatly tied. The potted plants should likewise be often refreshed with water, once or more in the day, when the season is hot. Those in the open ground should also be occasionally watered in dry weather. See **ANNUAL PLANTS**.

All these plants may be raised with great facility in the stove, in the same manner as above.

In the second species the seed may be sown either early in the spring, or in the autumn. In both the species those in the natural ground should be sown later than in the hot-bed method.

In order to save seed, a few of the best plants, of the different finest varieties, should be placed, when in full blow, in some airy situation, so as to be exposed to the sun, and at the same time protected from wet by glasses.

The fine potted species and varieties of these plants are highly ornamental among other potted plants, in the most conspicuous places about the houses; and the less valuable kinds in the fronts of the borders, clumps, and other parts of pleasure-grounds, in mixture with other flowery plants.

INARCH-GRAFTING. See **GRAFTING**.

INARCHING, a method of grafting by which the parts of different trees are bent down and united, while the trees remain growing. See **GRAFTING**.

INDIGO. See **INDIGOFERA**.

INDIGO, BASTARD. See **AMORPHA**.

INDIGOFERA, a genus containing plants of the shrubby exotic kind.

It belongs to the class and order *Diadelphia Decandria*, and ranks in the natural order of *Papilionaceæ* or *Leguminosæ*.

The characters are: that the calyx is a one-

leafed perianthium, spreading, nearly flat, five-toothed: the corolla papilionaceous: standard rounded, reflex, emarginate, spreading: wings oblong, obtuse, spreading at the interior margin, of the shape of the standard: keel obtuse, spreading, deflex, marked on each side by an awl-shaped hollow dagger or point: the stamina have diadelphous filaments, disposed in a cylinder, ascending at their tips: anthers roundish: the pistillum is a cylindric germ: style short, ascending: stigma obtuse: the pericarpium is a roundish long legume (linear-oblong, commonly four-cornered): the seeds some, kidney-shaped (kidney-retuse or cuboid).

The species cultivated are: 1. *I. tinctoria*, Dyer's Indigo; 2. *I. argentea*, Silvery-leaved Indigo; 3. *I. candicans*, White Indigo; 4. *I. amara*, Scarlet-flowered Indigo.

The first has the stem filiform, subflexuose, angular, smooth, upright, a foot and half high, a little branched at top: the branches like the stem, alternate, upright: the leaflets in four pairs or more, very blunt with a point, smooth, very finely villose underneath, almost equal: the racemes from the axils of the leaves, when they begin to flower, much shorter than the leaf, but becoming longer as they advance: the legumes drooping, subcolumnar, sharp, straight, very finely villose. It is a native of the East Indies.

The second species has the whole plant silky and glaucous: the stem suffruticose, upright, branched, round, from half a yard to three quarters of a yard in height, and gray: branches alternate, stiff, round, finely silky, and hoary: the leaves alternate, petioled, two-paired (seldom ternate), spreading, three inches long: leaflets opposite, subsessile (the end one larger and petioled), quite entire, bluntish, the older ones subemarginate, the midrib raised only underneath, finely silky, glaucous, spreading, flat, from twelve to fifteen lines in length, and from six to eight lines in breadth: the petioles round on one side, grooved on the other: the racemes axillary, solitary, upright, shorter than the leaves, an inch and half long: the flowers on short, alternate, reflex pedicels, and drooping. It is a native of Egypt or the West Indies.

The third is distinguished by the whiteness of the stem and the under-side of the leaves: the flowers are red, not many (five to eight or nine) in a spike. It is a native of the Cape, flowering from July to September: but its principal time of flowering, according to Mr. Curtis, is from the beginning of May to the middle of June.

The fourth is a native of the Cape, flowering in March and April.

Culture.—The first sort of these plants may

be increased by seeds, which should be sown in the spring, in pots of light fresh earth, and plunged into a mild hot-bed. When the plants have attained some growth, they should be removed into separate pots, and be replunged in the bark-bed of the stove, where they must be constantly kept.

The other sorts may be propagated by planting cuttings of the young shoots, in pots of good fresh earth, in the spring or summer, plunging them in the bark hot-bed of the stove. When they have stricken good root, they should be removed into separate pots of the same sort of mould, preserving some earth about their roots, replunging them in the hot-bed, due shade and water being given. They may afterwards be preserved in a dry stove or good green-house.

Such of the sorts as ripen seeds here may also be increased in that way.

The first is the plant from which Indigo, a material much employed in dyeing, is prepared.

This and the second kind also afford variety in stove collections; and the two others among plants of the green-house kinds.

INOCULATING, the practice of inserting the buds of trees of the same kind into their stocks.

The most proper season for this sort of work is, from the middle of June until the middle of August, according to the forwardness of the season, and the particular sorts of trees to be increased; but it may be easily known, by trying whether the buds will come off well from the wood or not. The most general rule is, when the buds are found to be formed at the extremity of the same year's shoots, which is a sign of their having finished their vernal growth. The first sort commonly inoculated is the Apricot, and the last that of the Orange-tree, which should never be done until the middle of August. In doing this sort of work, choice should be made of cloudy weather; as, when done in the middle of the day, in very hot weather, the shoots perspire so fast as to leave the buds destitute of moisture; nor should the cuttings be taken off from the trees long before they are used; but if fetched from some distance, the leaves should be cut off, but all the foot-stalks left, and then wrapped up in wet moss, and put in a tin box, to exclude the external air.

And the practice of throwing cuttings into water is improper; as it saturates the buds so with moisture, that they have no attractive force left to imbibe the sap of the stock; for want of which they very often miscarry, and disappoint the operator.

It is remarked by Mr. Forsyth, that when the Pear-trees which are grafted in the spring

have not taken, he would advise the cutting them off, a little below the graft, at a joint or bud. The tree then throws out a great number of healthy shoots; all of which should be rubbed off, except so many as are sufficient to fill the wall; nailing those up, to prevent the wind from breaking them. About the latter end of July the shoots will be fit to inoculate, which should then be done, leaving a little of the wood on the inside of the bud when inserted into the stock, and rubbing in some of the composition, tying on the bass.

Having grafted some summer Bonchrétiens with the Bergamot de Pasque (or Easter Bergamot) and Pear d'Auch, in the spring, most of which failed, he cut them off below the grafts, and in July following they had produced shoots from five to six feet long, which he inoculated in the latter end of that month with the before-mentioned sorts, which all took. About the beginning of September he ordered the basses to be slackened; which being left too loose, the barks began to separate. He then made them be tightened, letting them remain till the following spring. About the beginning of April, when he saw the buds begin to shoot, he cut the shoots near to the buds; but finding many where the bark had not united, and some of the eyes apparently dead, he took a sharp pen-knife, and cut out all the decayed bark, rubbing in some of the composition, in the liquid state, till the hollow parts were filled up; he then smoothed it off with the finger, even with the bark of the stock. He also rubbed some of the composition over those eyes that were in the worst state, being quite black; but with very little hope of recovery. "To his great astonishment, many of those which seemed perfectly dead, recovered, and by the middle of July had shoots from five to six feet long (many of the shoots which took well having fruit-buds formed for next year), and covered a space of wall larger than a young tree would have done in eight years; all the cavities where he cut out the dead bark and applied the composition, were, in the course of the summer, filled up with sound wood, and the bark between the stocks and grafts perfectly united."

"Three years ago he inoculated some Brown Beurrés and Crasanes with Pear d'Auch, one of which now covers a wall sixteen feet high, and fifteen feet long, and has more fruit on it this year than a maiden tree would have produced twenty years after planting." But he "never recommends inoculating or grafting of old trees, except when bad sorts, or more of any sort is wanted for a supply: in that case, he would recommend to inoculate or graft with Pear

d'Auch, Colmars, and Winter Bonchrétiens, which keep much longer than Beurrés, Crasancs, &c."

For standards that have been grafted in the spring, and have missed, he advises that they should be cut below the graft, as, when so treated, they throw out a great number of shoots, which should by no means be too soon thinned, as in that case they will be liable to be broken by the wind. The weakest shoots may be begun to be taken off about the latter end of May or beginning of June. About the middle of the latter month, they will have acquired considerable strength: then thin them; leaving as many strong regular shoots, and of those nearest the top of the stem, as will form a handsome head. If the stem be very strong it will be necessary, perhaps, to leave more than are intended to be inoculated, on purpose to receive the sap, which will flow in great abundance from a large trunk, and, without this precaution, be apt to burst the shoots. He has often seen shoots as large as his arm burst by a superabundance of sap. When that is likely to happen, the best thing is, to scarify the shoots, and rub a little of the composition into the wounds.

INSECT DISEASES, such vegetable diseases as are produced by different sorts of animals of the insect tribe. See **VEGETABLE INSECT DISEASES**.

The chief insects that affect plants of the fruit-tree kinds, are those of *Aphis*, *Acarus*, *Ant*, *Chermes*, *Cicada*, *Coccus*, *Earwig*, *Papiño*, *Phalæna*, and *Thrips* tribes.

Of the first sort there are a vast number of species, each tree being said to be infested by a different distinct species. Hence the author of the *Systema Vegetabilium* has denominated them from the trees on which they are found; as, the Cherry *Aphis*, Currant *Aphis*, Plum *Aphis*, &c. The males are few in comparison with the females, and have wings, while the latter are numerous, and without them. See **PUCERON** and **VINE-FRETTER**.

The second is a highly destructive insect in houses where forcing is practised. It is not furnished with wings, but the female is oviparous. The species, as in the former, are very numerous. It often commits great mischief on vines, peaches, nectarines, cherries, forced kidney-beans, melons, &c. See **RED SPIDER**.

The third, or *Ant*, is highly injurious to fruits, especially those of the peach kind, as they become in a state of maturity. They run all over the trees, and the best fruit is occasionally filled with them. It has been supposed by some that they are of use by devouring the Aphides on the trees; but Mr. Forsyth is of a different opi-

nion, and we have often seen fruit much spoiled by them.

The best methods of destroying them, according to the above author, is, by making holes in the ground along the side of the wall where the fruit-trees are, by an iron crow, so that the inside surface may be quite smooth. These insects, from being disturbed, soon come to the holes, and fall into them; when, being prevented from getting up by the smoothness of the sides, they may be readily destroyed by pouring water upon them. But more effectual methods are, either by mixing quick-lime with soot, and placing it in their tracks, or putting it in their nests, and then pouring water, or urine and soap-suds, upon it, so as to slake it, confining the heat by a turf, or some earth. The heat thus produced soon destroys them. The powder of stavesacre laid round the stems of trees, is said to prevent their running up them.

The fourth, or *Chermes*, belongs to the order *Hemiptera*.

There are several species. Their specific names are taken from the different plants on which they are principally met with; as the *Chermes graminis*, or Grass Bug; *Chermes ficus*, or Fig-tree Bug, &c. The last is one of the largest of the genus, being brown above and greenish beneath, and has four long wings, placed in the form of an acute roof. The larva is of an oblong form, and has six feet, but its motion is slow. When attempted to be caught, the *Chermes* makes its escape rather by leaping than flying, by means of its hinder legs, which play like springs. Several of the species are provided at the extremity of their bodies with small sharp-pointed implements, but which lie concealed; and these they draw out in order to deposit their eggs, by making punctures in the plants that suit them. It is in this way that the Fir-tree *Chermes* produces that enormous scaly protuberance which is sometimes found at the summit of the branches, and which is formed by the extravasation of the juices occasioned by the punctures. The young larvæ shelter themselves in cells contained in the tumour. These insects are capable of being destroyed in the same manner as the *Cocci* tribe.

The fifth, or *Cicada*, belongs to the same order as the above.

The larvæ of many of this tribe void large quantities of frothy matter upon the leaves and branches of the plants and trees, in the midst of which they are always concealed, probably for protection, and to be shaded from the sun's influence. These insects should be destroyed, as the froth is unpleasant, and the leaves of the trees are often devoured, by rubbing off the

larvæ with the hand, and afterwards watering the trees well with soft water, such as that of ponds.

The sixth, or *Coccus*, also belongs to the same order, and the males have wings, but the females none.

The sorts most commonly met with, when full grown, have somewhat the form of a boat, with the keel uppermost, being apparently without feet, eyes, &c. while in this state resembling some sorts of galls or excrescences of the bark of trees.

Mr. Forsyth observes, that "a thin film of a white cotton-like substance is interposed between the flat part of the body and the tree. This is common, in a greater or lesser quantity, to all the species, and appears at first all round the edge as a kind of cement, to join it to the tree. The males are very few in proportion to the females, and not nearly one-fourth of their size; they are beautiful little flies, which, after a short but active life, terminate their existence without having tasted food, being provided with no sort of organs for that purpose."

"The Peach, Nectarine, and Pear Trees are very much infested with these insects: they frequently cut through the bark, and the trees then appear as if they had been scratched by cats." He has "seen some with this appearance all over them."

He advises, that "when these insects first appear on the bark, they should be scraped off with a wooden knife, and the stem and branches of the tree well washed with soap-suds and urine, applied with a stiff painter's brush. This should be done in February, before the buds begin to come out. But if the outer bark is perforated, it must be cut or pared off with a long knife; and if you find any brown spots in the inner bark, they must be carefully cut out. This disease is, he thinks, one great cause of the canker, and of the death of the tree."

And it is added, that "when this disease has made its way through both barks, as is often the case, the branches on each side of the tree may be cut close to the stem, if it has an upright one; but if the tree be trained fan-fashion, the best way is to head it near to the place where it was grafted."

He has "headed old Pear-trees which were so dead, except a small strip of live bark on one side, that you might rub the bark off them as easily as off a bundle of faggot-sticks that had been cut upwards of a year; yet these trees have shot out fresh branches to the length of seventeen feet in two years, and produced fine fruit the second year." It is advised to apply the composition immediately after heading, or cutting, or paring off the diseased bark.

It is further remarked, that "a very destructive species of the *Coccus* tribe has lately done incredible damage to the Apple-trees in the nurseries and gardens in the neighbourhood of London. Some nurserymen have lost several thousand Apple-trees in one year. These insects attach themselves to the bark by their suckers, and, by feeding on the juices of the tree, rob it of its nourishment. Such trees as are infested with them have a sickly appearance. These insects generally make their nests where branches have been cut off, or in hollow places, where the canker has eaten holes in the trees. Their first appearance is like a white down; on touching or rubbing them, they tinge the fingers of a crimson colour, like cochineal. If suffered to remain long on trees, they take wing, like Aphides."

The method that he has followed for these ten years to destroy them, is, to "rub the places where their nests are with an old brush, such as painters use, till they are all cleaned off; and if the part be canker-eaten, to cut it clean out with a knife or chisel: he then takes of soap-suds and urine equal parts, and with this he washes the wound and the bark all round it; and with a brush applies the composition, mixed with wood-ashes and the powder of burnt bones, covering the wound all over with it. Afterwards he shakes some of the powder of wood-ashes and burnt bones, mixed with an eighth part of unslaked lime finely powdered and sifted, over the hollows, or where knobs have been cut off."

And he advises, that "at the same time that the trees are cleared of the cocci the caterpillars should be picked off."

He adds, that "the first time that he observed the new *coccus* which has done so much mischief to the Apple-trees about London, was in a garden of his own at Chelsea, about the year 1782 or 3; and, as far as he can learn, they were imported, among some Apple-trees, by the late Mr. Swinton, of Sloane-street. Mr. Swinton afterwards removed his nursery to the King's Road, near Chelsea College, which now goes by the name of the Foreign Nursery."

Train oil has been tried, laid on with a painter's brush, but without effect.

The seventh, or *Earwig*, is often very destructive to fruit, particularly that of the Peach kind. The method recommended by Mr. Forsyth for destroying them, and which he has long pursued with success, is, to "take old bean-stalks, and cut them about nine inches long, tying them up in small bundles with some pack-thread, or with small yellow willows, and hanging them on nails against the wall, at different parts of the trees. The first thing in the morning, be-

ing provided with a board about eighteen inches square, and a small wooden trowel, take down the bundles of bean-stalks, one by one, strike them against the board, and with your trowel kill the Earwigs as they fall out of the stalks. If you follow this up every morning (or every other morning) you will be able to keep them under."

This method answers for any sort of trees infested with Earwigs. In some years he has "seen a great part of the fruit, especially the smooth-skinned sorts, destroyed by these insects, and a small green caterpillar; and in a scarce year of fruit, the leaves of peaches are frequently destroyed by them." It is advised, that "the shreds taken from trees that have been unnailed in autumn, should be soaked in boiling hot soap-suds for three or four days, previous to their being used again; as this will kill the eggs of Earwigs and other insects that may be deposited on them."

The eighth, *Papilio*, or Butterfly, belongs to the order *Lepidoptera*.

There are a great many species of this genus, mostly distinguished by the colour of their wings. The more common sorts, with their caterpillars, are well known.

Mr. Forsyth advises, that the caterpillars and chrysalids should be carefully picked off, and the trees be well watered with clear lime-water and tobacco-water mixed.

The ninth, *Phalæna*, or Moth kind, are extremely numerous, their caterpillars differing much in size, shape and colour. After casting their slough several times, all of them spin their cod, in which they are transformed to chrysalids. In this state they are often found rolled up in the leaves of fruit-trees, especially those of the pear, plum, and cherry kind. See *PHALÆNA*.

Of the *Sphinx*, or Hawk Moth kind, there are a vast number of species. Their caterpillars apply the hinder part of their bodies to the branches of trees, holding the rest erect; hence the name. In general they spin their cod under ground.

They appear early in the morning, or after sun-set, flying heavily, and making a sort of noise. Several of the caterpillars are green, and some brown, yellow, spotted, or belted. See *PHALÆNA*.

The *Phalæna nustria*, or Lackey Moth, deposits its eggs in rings or circles round the branches of fruit-trees, having the appearance of a necklace. See *PHALÆNA*.

The tenth, or *Thrips*, belongs to the order *Hemiptera*; and there are several species. It is extremely small, so as scarcely to be discovered. It produces much mischief on fruit-trees, devouring the fruit as well as the leaves.

It may be destroyed in the same manner as the Coccis.

The pernicious effects of these different insects, as well as the means of removing them, will be more fully explained in speaking of those vegetable diseases that are caused by the attacks of insects. See *VEGETABLE INSECT DISEASES*.

INULA, a genus comprehending plants of the herbaceous and shrubby kind.

It belongs to the class and order *Syngenesia Polygamia Superflua*, and ranks in the natural order of *Compositæ Discoideæ*.

The characters are: that the calyx is common imbricated: leaflets lax, spreading: the exterior ones larger, of equal length: the corolla compound, radiated, broad: corollules hermaphrodite, equal, very numerous in the disk: females strap-shaped, numerous, crowded, in the ray: proper of the hermaphrodite, funnel-form: border five-cleft, rather upright: female strap-shaped, linear, perfectly entire: the stamens in the hermaphrodite have five filaments, filiform, short: anther cylindric, composed of five smaller linear conjoined ones; each ending below in two straight bristles of the length of the filaments: the pistillum in the hermaphrodite is an oblong germ: style filiform, length of the stamens: stigma bifid, rather upright: in the females, germ long: style filiform, half bifid: stigmas erect: there is no pericarpium: the calyx unchanged: the seeds in the hermaphrodites solitary, linear, four-cornered: pappus capillary, length of the seeds: in the females like the hermaphrodites: the receptacle naked, flat.

The species cultivated are: 1. *I. Helenium*, Common Inula, or Elecampane; 2. *I. Britannica*, Creeping-rooted Inula; 3. *I. salicina*, Willow-leaved Inula; 4. *I. Canariensis*, Canary Inula; 5. *I. satureioides*, Savory-leaved Inula; 6. *I. fruticosa*, Shrubby Inula.

The first has a perennial, thick, fusiform, brown, branching, aromatic root; according to some, biennial: it is one of the largest herbaceous plants, being from three to five or six feet high, with the stem striated and downy, branched towards the top: the lower leaves on foot-stalks, lanceolate, a foot long, and four inches broad in the middle; upper embracing, ovate-lanceolate, wrinkled, serrated or toothed, deep green, and slightly hairy above, whitish green and thickly downy beneath: the flowering heads very large, single, terminating the stem and branches. It is a native of Japan, &c. flowering in June and July.

The second species has a perennial root: the stem near two feet high, dividing in the upper part into two or three upright branches or pe-

duncles, each sustaining one pretty large flower, of a deep yellow colour. These are in beauty in July, but seldom ripen seeds in this climate. It is a native of Germany, &c.

The third has a perennial root, aromatic, sub-astringent, smelling like cinnamon: the stem from a foot to two, and even three feet in height, upright, smooth, hard, firm, tinged with red, grooved or angular towards the top, where it is usually branched: the leaves alternate, sessile, or half embracing, stiff, smooth, of a dark shining green, very slightly cut, and somewhat rugged about the edge: the flowers terminating, on alternate, one-flowered, grooved, reddish peduncles, forming altogether a corymb: the calycine scales in two rows, smooth, brown, lanceolate, curved back a little at the end: the flower an inch in diameter. It is a native of Germany, &c.

The fourth rises with several shrubby stalks near four feet high, which divide into smaller branches: the leaves in clusters, narrow, fleshy, divided into three segments at their points: the flowers come out on the side of the branches at the top of the stalks; they are small, and of a pale yellow colour, appearing in August. It is a native of the Canary islands.

The fifth rises with a shrubby stalk about two feet high, dividing into many smaller branches, which are hairy: the leaves narrow, stiff, sessile; from the edges of these arise long hairs, which are stiff, and come out by pairs; at the end of the branches arise naked peduncles, four or five inches long, sustaining one small, yellow, radiated flower. It is a native of Vera Cruz.

The sixth has a stem ten or twelve feet high, divided into several woody branches: the leaves five inches long, and one inch and a half broad in the middle, smooth on the upper side, but on their under having three longitudinal veins: the flowers are produced at the end of the branches, having very large scaly calyxes; they are as large as a small Sun-flower, of a pale yellow colour. It is a native of Carthage in New Spain.

Other species may be cultivated.

Culture.—The first sort may be propagated by seeds sown in autumn soon after they are ripe, on a warm, loamy, rather moist border. The plants should be transplanted to the places where they are to grow in the following autumn.

But the common practice is to increase it by offsets, which, when taken from the old roots carefully, with a bud or eye to each, take root easily: the best season is the autumn, as soon as the leaves begin to decay; planting them in rows about a foot asunder, and nine or ten inches distance in the rows. The following

spring the ground should be kept clean from weeds, and be slightly dug over in the autumn following. The roots will be fit for use after two years growth, but will abide many years if permitted to stand.

The two following sorts may be increased by parting the roots, and planting them in the autumn, in the borders or other places where they are to remain. They should not be removed oftener than every three years.

The fourth and fifth sorts may be raised by planting cuttings of the branches, in the summer season, in pots of light earth, in shady borders. They must be removed into shelter in autumn, but should have as much free air as possible at all times, when the weather is mild. In cold weather the first should have but very little water, as, the stalks and leaves being succulent, they are very apt to rot. In summer they should be placed abroad with other hardy exotic plants, in a sheltered situation.

The last sort is propagated by seeds procured from where it grows naturally. These must be sown in pots, or upon a hot-bed, and when the plants are fit to remove, be each put into a small pot filled with light earth, and plunged into a fresh hot-bed; treating them in the same manner as other similar tender plants. It requires to be kept constantly in the stove.

The first sort may be cultivated for the medicinal use of the roots, or for ornament, in large borders.

The two following sorts may have places in the same way.

The fourth and fifth kinds afford variety among other potted green-house plants, and the last among stove plants.

IPOMŒA, a genus containing plants of the herbaceous flowery kind.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Campanaceæ*.

The characters are: that the calyx is a five-toothed perianthium, oblong, very small, permanent: the corolla one-petalled, funnel-form: tube subcylindric, very long: border five-cleft, spreading: divisions oblong, flat: the stamina have five awl-shaped filaments, almost the length of the corolla: anthers roundish: the pistillum is a roundish germ: style filiform, length of the corolla: stigma headed-globose: the pericarpium is a roundish capsule, three-celled: the seeds some, sub-obovate.

The species cultivated are: 1. *I. Quamoclit*, Winged-leaved Ipomœa; 2. *I. coccinea*, Scarlet-flowered Ipomœa.

The first is an annual plant, rising with two oblong pretty broad seed-leaves, which remain

Various coloured Iris

3 *Iris variegata*
Variegated Iris

a considerable time before they fall off: the stems slender, twining, and rising by support to the height of seven or eight feet; sending out several side-branches, which twine about each other and the principal stem, and about any neighbouring plants: the leaves are composed of several pairs of very fine narrow lobes, not thicker than fine sewing thread, about an inch long, of a deep green, either opposite or alternate: the flowers come out singly from the side of the stalks, on slender peduncles about an inch long: the tube of the corolla is about the same length, narrow at bottom, but gradually widening to the top; where it spreads open flat, with five angles; it is of a most beautiful scarlet colour, and makes a fine appearance. It is a native of the Indies.

The second species has a herbaceous stem, twining, quadrangular, flexuose: the leaves petioled pentangular, smooth on both sides: the peduncles very long, axillary, upright, round, two-parted-bifid, on one-flowered pedicels: the flowers long, scarlet, larger than those of the first sort: calyx five-cleft, with lanceolate segments: tube of the corolla narrower at the base, long, columnar, curved a little, and shining: border plaited, blunt: base nectareous. It is an annual plant, six or eight feet high, and a native of the West Indies.

There is a variety with orange-coloured flowers,

Culture.—These plants are increased by sowing the well ripened seed in small pots, plunging them in a mild hot-bed, or in the earth of the bed, in the early spring months, proper air and water being given. When the plants have attained some growth, and in the first sort begin to climb, they should be removed with balls of earth about their roots into the places where they are to grow, or, which is better for the first kind, into separate large pots, replunging them in the bark hot-bed. They should have proper sticks set for them to twine about, some pots of the first kind being placed in the stove, as being more tender.

The first sort affords variety in the stove, and among other tender potted plants in the summer; and the latter in the fronts of warm borders, as well as among the less tender potted flowering plants.

IRIS, a genus containing plants of the fibrous, tuberous, and bulbous-rooted flowery herbaceous perennial kinds.

It belongs to the class and order *Triandria Monogynia*, and ranks in the natural order of *Ensatae*.

The characters are: that the calyx has bivalve spathes, separating the flowers, permanent: the corolla six-parted: petals oblong, obtuse; the

VOL. II.

three exterior ones reflex, the three interior upright and sharper; all connected at the claws into a tube, of different lengths in the different species: the stamens have three awl-shaped filaments, incumbent on the reflex petals: anthers oblong, straight, depressed: the pistillum is an inferior oblong germ: style simple, very short: stigmas three, petal-form, oblong, carinated within, furrowed without, incumbent on the stamens, two-lipped: outer lip smaller, emarginate: inner larger, bifid, subinflected: the pericarpium is an oblong, cornered capsule, three-celled, three-valved: the seeds several and large.

The species cultivated are: 1. *I. pumila*, Dwarf Iris; 2. *I. susiana*, Chalcedonian Iris; 3. *I. Florentia*, Florentine Iris; 4. *I. biflora*, Twice-flowering Iris; 5. *I. aphylla*, Leafless Iris; 6. *I. variegata*, Variegated Iris; 7. *I. Germanica*, German Iris; 8. *I. sambucina*, Elder-scented Iris; 9. *I. squalens*, Brown-flowered Iris; 10. *I. cristata*, Crested Iris; 11. *I. tricuspidis*, Trifid-petalled Iris; 12. *I. Xiphium*, Bulbous-rooted Iris; 13. *I. Pseudacorus*, Common Yellow or Water Iris; 14. *I. foetidissima*, Stinking Iris; 15. *I. Virginica*, Virginian Iris; 16. *I. versicolor*, Various-coloured Iris; 17. *I. ochroleuca*, Pale-yellow Iris; 18. *I. verna*, Spring Iris; 19. *I. Persica*, Persian Iris; 20. *I. graminea*, Grass-leaved Iris; 21. *I. spuria*, Spurious Iris; 22. *I. Sibirica*, Siberian Iris; 23. *I. Martinicensis*, Martinico Iris; 24. *I. Pavonia*, Peacock Iris; 25. *I. tuberosa*, Snake's-head Iris.

The first has the root brownish on the outside, white within, knobbed, with pale fibrils: the leaves acute, sometimes shorter, sometimes longer than the flower: the stem or scape very short, often scarcely an inch in length: germ oblong, bluntly and obscurely three-cornered, an inch long, inclosed within two spathes, ending in the tube of the corolla, which is slender, and from two to three inches in length: all the petals are almost entire, blue or purple, varying much in colour, insomuch that the same flower changes, and from blue becomes more and more red: outer beards blue, inner white, with yellow tips. It is a native of Austria, flowering in April.

There are varieties with white flowers, with straw-coloured flowers, with pale blue flowers, with blush-coloured flowers, with yellow variable flowers, with blue variable flowers.

The second species has the scape simple, round, grooved, a span high: the leaves alternate, sheathing, upright, very finely striated, obscurely waved: the corolla the largest of all the species, very thin: the claws of the larger petals purple on the outside, dotted and streaked

D

with purple within; border suborbiculate, waved, bent in at top, upright; border of the smaller petals ovate, bent down, with the edge frequently bent back, blunt, of the same colour with the larger ones, but shorter and narrower; the claws bearded within from the flexure to the base with brownish-yellow cilia. It flowers at the end of May or beginning of June, and is a native of the Levant.

The third has the scape round, striated, simple, upright, a foot high and more, bearing two or three flowers: the leaves nerved, subfalcated, obscurely curved on the outer edge: the lower petals connate at the base: the claws of the larger ones thickish, with a thin winged edge, an inch long, green on the outside, bearded within, with white cilia, yellow at the top: border blunt, emarginate, an inch wide, a little more in length, hanging down, white, striated near the flexure: smaller petals oblong, from upright bent in with a reflex margin, blunt, emarginate, white: claws thickish, attenuated, greenish. It is a native of the South of Europe, flowering in May and June.

The fourth species has the scape simple, striated, longer than the leaves, a span in height, sustaining two or three flowers, sometimes four: the leaves subfalcated, acute, striated, from erect patulous: the petals violet-coloured, entire: capsule cylindric, with three streaks. It is a native of Portugal, flowering in April and May, and again in autumn, whence the name.

The fifth has three or four large bright purple flowers, which stand above each other, and have purplish sheaths: the three bending petals or falls are striped with white from the base to the end of the beard: the capsules are large, blunt, and triangular. It flowers at the end of May. Its native place is unknown.

The sixth species has the scape striated, scarcely longer than the leaves, a foot and more in height: leaves acute, striated, upright; the lower ones the length of the scape, but the upper ones gradually shorter: the flowers at the top of the scape divided, alternate, coming out successively, handsome, yellow, netted with black: the upper part of the stem is naked, and divides into three branches, each of which has two or three flowers one above another: the three upright petals or standards are yellow, and the bending petals or falls are variegated with purple stripes. It flowers in June, and is a native of Hungary.

The seventh has the scape divided at top, larger than the leaves: the leaves reflex-falcated, nerved, an inch wide: the flowers blue, with the smaller petals quite entire, having an agreeable scent: the stalks rise near four feet high, and

divide into several branches, each supporting three or four flowers, which are covered with a thin sheath; the three bending petals or falls are of a faint purple inclining to blue, with purple veins running lengthwise: the beard is yellow, and three erect petals or standards are of a bright blue, with some faint purple stripes. It is a native of Germany, flowering in May and June.

The eighth species has the scape divided at top, longer than the leaves, two (or three) feet high: the leaves inflex-falcated at top, striated, the upper ones gradually shorter. It resembles the seventh, from which it differs in having the larger petals of a deeper violet colour, and sub-emarginate; the smaller petals emarginate, and of a deeper blue colour: the stigmas acute and serrate, with a blueish keel. It derives the trivial name from the smell of the flowers, which is very like that of Elder in bloom. It flowers at the end of May, and in June, and is a native of the South of Europe.

In the ninth, the roots are very thick, fleshy, and divided into joints, spreading just under the surface of the ground: they are of a brownish colour on their outside, but white within: the leaves rise in clusters, embracing each other at their base, but spread asunder upwards in form of wings: they are a foot and a half long, and two inches broad, having sharp edges, ending in points like swords: the stalks between these, which are a little longer than the leaves, having at each joint one leaf without a foot-stalk; these diminish in their size upwards: the stalks divide into three branches, each of which produces two or three flowers one above another at distances, each inclosed in a sheath: they have three large violet-coloured petals which turn backward, and are called falls: these have beards near an inch long on their midrib towards their base, and have a short arched petal which covers the beard, with three broad erect petals of the same colour, called standards: the stamina lie upon the reflexed petals. It flowers in June. It is a native of the South of Europe.

There are varieties with blue standards and purple falls, with pale purple standards, with white standards, and with a smaller flower.

The tenth species has a tuberous, creeping root: the stems several, short, inclining upwards, compressed, leafy: the leaves scarcely six inches long, sharpish, a little curved like a sickle at the tips, entire, with a pale membranaceous margin: the flower generally solitary, a little shorter than the leaves, erect, of a pale purplish blue: outer petals drooping, obtuse, blue, with deeper blue spots, crested in the place of the beard with three longitudinal, elevated, waved ribs, variegated with orange and yellow; inner petals narrower,

pointed, uniform in colour. It is a native of North America; flowering in May.

In the eleventh species, the bulb is the size of a hazel nut: the scape simple, round, jointed, upright, bearing one or two flowers, a foot and half in height: the leaf single, nerved, upright, with the tip hanging down, two feet long: the border of the larger petals white, suborbiculate, with a point; claws green on the outside, yellow within, dotted with black: the smaller petals several times shorter and less: claws convex on the outside, green, concave within, dotted with brown, the length of the larger ones, but narrower; segments lanceolate, divaricating, a line in length, the middle one of the three a little longer, white dotted with brown. It is a native of the Cape.

It varies in the shape of the larger petals, and much in the colours, as blue, purple, yellow, white, and spotted.

The twelfth has the leaves channelled and convoluted, not only at the base, as in the other species, but the whole length of them; they are awl-shaped at the tip, and shorter than the scape: the flowers are blue, with emarginate petals. It is a native of the South of Europe.

There are varieties with blue flowers, with violet-coloured flowers, with white flowers, with purple flowers, with yellow flowers, with blue standard petals and white falls, with blue standards and yellow falls, with striped flowers, the broad-leaved with blue flowers, the broad-leaved purple-flowered, the sweet-scented blue-flowered, the sweet-scented purple flowered, with variegated sweet-scented flowers, and the double-flowered.

The thirteenth has a fleshy root, the thickness of the thumb, spreading horizontally near the surface, blackish on the outside, reddish and spongy within, the upper part covered with numerous ridged fibres, the lower part sending down many long, whitish, wrinkled, stringy roots: the leaves from the root two or three feet long, upright, an inch or more in breadth, striated, having a prominent longitudinal midrib, equal to the scape, deep green, smooth: stem-leaves shorter, forming a sheath at the bottom: scapes from one to three feet in height, upright, alternately inclined from joint to joint, round or flattened a little, smooth and spongy: the peduncles axillary, flat on one side, and smooth; each sustaining two or three flowers, the two outer (when there are three) having one sheath, and middle flower two. It is common in most parts of Europe; flowering at the end of June, or the beginning of July.

The fourteenth species has a thick, tufted, fibrous root: the leaves grass-green, when broken emitting a strong odour, not much unlike that of

hot roast beef at the first scent. They are acute and nerved; rather shorter than the scape; which is single, cylindrical, but angular on one side, jointed, sheathed with alternate spathaceous leaves, two feet high, bearing several flowers. It is a native of France, &c.

The fifteenth has the root white within, black without, the thickness of the thumb, having white fibres, and bristly at top, with the remains of leaves: the scape compressed, upright, jointed, sheathed with alternate leaves, many-flowered, the length of the leaves, or a little higher, a foot in length: the leaves narrow, sharp, curved-in at the tip, nerved and smooth, as is the whole plant: the spathes membranaceous, acute, brownish, shorter than the peduncles, very thin at the edge and tip: the peduncles two or three inches long, round, slender, upright, one-flowered: the flowers elegant, but without scent: claws of the outer petals channelled, green on the outside, yellow on the inside, streaked with dark purple: border flat, rounded-ovate, blunt, quite entire, pale at the base, then blue with deep-blue streaks: inner petals spatulate, blunt, upright, shorter, bluer and streaked. It is a native of Virginia, flowering here in June and July.

The sixteenth species has the scape jointed, bifid at the top, or simple, many-flowered, higher than the leaves, two feet in length: the leaves alternate, sheathing; the upper ones gradually shorter: the flowers blue, large. Mr. Curtis remarks, that it has, for the most part, a stalk unusually crooked or elbowed. It is a native of North America, flowering in May and June.

The seventeenth has the scape round or roundish, covered with the sheaths of leaves, many-flowered, longer than the leaves, a foot high: the leaves falcated, acute, striated, nerved: spathes membranaceous at the edge: the larger petals dilated at the base with dusky veins; lesser snowy-white, with yellowish veins at the base: stigmas snowy-white. From its being the highest of the species of *Iris* cultivated in gardens, Mr. Curtis has named it *Tall Iris*. It is a native of the Levant, flowering in July.

The eighteenth species has tufted fibrous roots, from which arise many grass-like leaves about nine inches long; from between them come out the stalks, which are shorter than the leaves, and support one purple flower with blue standards. It flowers in May, and is a native of North America.

The nineteenth has an oval bulbous root, from which come out five or six pale-green leaves, hollowed like the keel of a boat, about six inches long, and one inch broad at the base, ending in points: between these the flower-stalk arises, which is seldom above three inches high, supporting one or two flowers, inclosed in spathes;

these have erect petals or standards, of a pale sky-blue colour, and three reflexed petals or falls, which on their outside are of the same colour, but the lip has a yellow streak running through the middle, and on each side are many dark spots, with one large deep-purple spot at the bottom: the leaves are striated and nerved, unequal, and a span in length. It is a native of Persia.

This is greatly esteemed for the beauty and extreme sweetness of its flowers, as also for its early appearance in the spring, being generally in perfection in February or the beginning of March, according to the season.

Martyn observes, that "like the Hyacinth and Narcissus, it will blow within doors in a water-glass, but stronger in a small pot of sand or sandy loam, and a few flowers will scent a whole apartment."

The twentieth species has narrow, flat, glass-like leaves, about a foot long, of a light-green colour; between these arise the stalks about six inches high, having two narrow leaves much longer than the stalks: the flowers two or three, small: the petals have a broad yellow line with purple stripes; the three falls are of a light purple colour striped with blue, and have a convex ridge running along them: the others are of a reddish purple variegated with violet; they have a scent like fresh plums. It is a native of Austria, flowering in June.

The twenty-first has a knobbed root, blackish on the outside, whitish within, with long pale fibres: the stem round, very slightly compressed, straight or a little flexuose, from two to three feet in height, taller than the leaves: the flowers commonly two, on short peduncles, each involved in its spathe; sometimes there are three; they have no scent: the colour blue-purple; but under the stigmas the reflex petals are more inclined to red: upright petals flat, and usually quite entire. According to Miller, the flowers have light blue standards, and purple variegated falls, having a broad white line in the middle instead of the beard. It is a native of Germany, &c. flowering in July.

The twenty-second species has a higher stem, the scape a foot high or more, dividing at top, three-flowered or many-flowered, longer than the leaves; which are nerved and flat: the flowers blue, in brown scariose spathes: the inner petals are upright: the germ trigonal, not grooved at the angles. It is a native of Siberia, &c. flowering in May and June.

The twenty-third has a solid sub-bulbose root, surrounded by whitish fibres, and throwing out other tubers: the stem upright, roundish, two feet high, simple: the root-leaves acuminate, quite entire, somewhat rigid, distich, flat, keeled

at the base, above simple, from upright spreading, few: the flowers few, coming out successively from the same spathe, yellow, without scent, peduncled: the petals have a black shining glandular hole or pit, like that which is common to several species of *Ranunculus*. It is a native of Martinico; flowering in November and December.

The twenty-fourth species has the scape round, jointed, villose, simple, a foot high, sustaining one or two flowers: the leaf somewhat channelled, striated, villose, the length of the scape: the spathes acute, striated, smooth, two inches long: the peduncles subancipital, one-flowered, smooth: all the petals united at the base: the three outer several times bigger than the others, ovate, obtuse, entire; the three inner much narrower and shorter by half, lanceolate, acute. This beautiful flower is orange-coloured, with black spots and dots at the base, and a heart-shaped blue spot above the base, which at bottom is tomentose and black. It is a native of the Cape.

The twenty-fifth has a tuberous root; there arise from it five or six long narrow four-cornered leaves, and from between these the stalk, supporting one small flower, of a dark purple colour. It flowers in April, but does not produce seeds in this climate. It is a native of the Levant.

Culture.—Most of the sorts may be readily increased, by parting the roots or separating the off-sets from the bulbs, and planting them out in the situations where they are to flower; the first sort in the autumn, or very early in the spring, and the latter in the close of summer, when the leaves decay, managing them in the same manner as other bulbs. As they increase and spread rapidly in their roots, they should be divided and taken off every two or three years.

New varieties of the different sorts may be raised from seed, by sowing it in the autumn in a bed of light sandy mould. The plants come up in the following spring, and in the autumn may be transplanted where they are to grow. They flower a year or two afterwards.

The bulbous-rooted sorts succeed best in such soils as are of the light, sandy, loamy kind.

The last sort answers most perfectly in such aspects as are towards the east, the roots being prevented from going too deep.

As the second sort is liable to be injured by severe winters, a few should be planted in pots to have protection. This sort is well suited for forcing.

When planted in the open ground, it requires a rather dry soil and situation.

The Cape sorts should be retained in the dry stove, and be propagated and managed in the same manner as other bulbous-rooted plants of the same kind.

All the sorts are proper for affording variety in the borders, clumps, and other parts of pleasure-grounds; and some of the more tender sorts among potted plants of similar growths.

IRON-WOOD. See *SIDEROXYLON*.

ITEA, a genus containing plants of the hardy deciduous shrubby kind.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Rhododendra*.

The characters are: that the calyx is a one-leaved perianthium, five-cleft, upright: segments lanceolate, acute, permanent, coloured: the corolla has five petals, sessile, lanceolate, acuminate, spreading, deciduous: the stamina have five awl-shaped, upright filaments, the length of the corolla, inserted into the base of the calyx: anthers roundish, incumbent: the pistillum is an ovate superior germ: style permanent, cylindrical, the length of the stamens: stigmas two, blunt: the pericarpium is an ovate capsule, longer than the calyx, mucronated by the style, two-celled, two-valved, many-seeded: the seeds very small, oblong, and shining.

The species cultivated are: 1. *I. Virginica*, Virginian Itca; 2. *I. cyrilla*, Entire-leaved Itca.

The first is a shrub six or seven feet high, sending out many branches from the bottom to top: the leaves are alternate, slightly serrate, reflex, veined, light green. At the extremity of the same year's shoots, in the month of July, are produced fine spikes of white flowers, three or four inches long, and erect. When this shrub is in vigour, it is entirely covered with these flowers, making a fine appearance. It is a native of North America.

The second species is also a shrub, three feet in height: the stem is upright, somewhat branched, round, ash-coloured: branches alternate or scattered, spreading, angular, rufous, smooth: the leaves alternate, bluntish, revolute, with the edges a little waved, one-nerved: the midrib marked with lines above, prominent underneath, smooth, paler underneath, dry, spreading, flat, permanent, three inches long, and an inch wide: the petioles very short, cylindric below, flat above, reddish: the racemes very many, lateral at the base of the new shoots, one from each bud, on short peduncles, spreading, from four to six inches long: the flowers are scattered, pedicelled, spreading, white, two or three lines in diameter. It is a native of Carolina, flowering in July and August.

Culture.—The first is capable of being in-

creased by layers, which should be laid down in the autumn, when they will put out roots so as to be fit to take off by the following autumn, when they may be removed into the nursery, or the places where they are to grow. It does not succeed well on dry gravelly soils.

It may also be raised from seed, by sowing it in the spring, as soon as procured from abroad.

The second sort may be increased by layers or cuttings, planted in pots of good mould in the spring; in the latter case, placing them in a mild hot-bed till they have stricken root, afterwards removing them into separate pots, placing them in airy situations in the green-house.

The first is very ornamental in the borders and clumps, and the latter among green-house collections.

IVA, a genus containing plants of the hardy, deciduous, shrubby, and herbaceous annual kinds.

It belongs to the class and order *Monœcia Pentandria*, and ranks in the natural order of *Compositæ Nucamentaceæ*.

The characters are: that the calyx is common roundish: leaflets about five, subovate, blunt; almost equal, permanent, containing very many florets: the corolla compound convex: corollets male, very many in the disk; female five in the ray; proper, males one-petalled, funnel-form, five-toothed, the length of the calyx; females none: stamina males, five filaments, bristle-shaped, the length of the corollet: anthers erect, approximating: the pistillum females, oblong germ, the length of the calyx: styles two, capillary, long: stigmas acute: there is no pericarpium: calyx unchanged: the seeds solitary, naked, the length of the calyx, at top thicker, blunt: the receptacle chaffy; chaffs linear, and interior.

The species are: 1. *I. annua*, Annual Iva; 2. *I. frutescens*, Shrubby Iva, or Bastard Jesuit's-bark-Tree.

The first is an annual plant, with an herbaceous stalk, rising from two to three feet high, sending out several branches from the sides: the leaves have three deep longitudinal veins and are serrate: the stalks and branches are terminated by small clusters of pale blue flowers, which appear in July, and the seeds ripen in autumn. It is a native of South America.

The second species has slender woody branches, eight or ten feet high: the leaves serrate: the branches terminated by small clusters of pale purple flowers. It is a native of Virginia, flowering in August.

Culture.—The first sort is raised by sowing the seeds on a moderate hot-bed in the spring, and when the plants are fit to remove, placing

them in another hot-bed, treating them as the less tender annual sorts.

In the second sort, the young branches should be layed down in the spring, when they will have put out roots in about six months; or cuttings may be planted in a shady border in May, and when they have taken root, removed with earth about their roots to the places where they are to grow. It succeeds best in a dry soil and warm sheltered situation.

The first affords ornament among the less tender annuals, and the latter in the warm borders and clumps in shrubberies.

JUDASTREE. See **CERCIS**.

JUGLANS, a genus containing plants of the hardy deciduous tree kind.

It belongs to the class and order *Monoecia Polyandria*, and ranks in the natural order of *Amentaceæ*.

The characters are: that in the male flowers the calyx is a cylindrical ament, imbricate-scattered all round, with one-flowered scales, turned outwards: perianthium elliptic, flat, six-parted: segments upright-concave, blunt: there is no corolla: the stamina have many filaments (eighteen to twenty-four, twelve to twenty-four) very short: anthers oval: female flowers heaped: the calyx is a one-leaved perianthium, bell-shaped, four-cleft, upright, very short, one-flowered: the corolla one-petalled, four-cleft, upright, acute, a little larger than the calyx: (none:) the pistillum is an oval germ, large, inferior: style very short: (styles two:) stigmas two, large, reflex, jagged at top: the pericarpium is a dry drupe, oval, large, one-celled: the seed a nut, very large, roundish, netted-grooved, half-four-celled: (corticated, two-valved: nucleus four-lobed, variously grooved.

The species cultivated are: 1. *J. regia*, Common Walnut-tree; 2. *J. alba*, White Walnut-tree, or Hickory; 3. *J. nigra*, Black Walnut-tree.

The first is a very large and lofty tree, with strong spreading boughs: the leaves pinnate, with a very strong but not unpleasant smell: the leaflets three pairs (sometimes two or four), nearly equal, except that the odd one is larger; they are entire, smooth, and shining: the male flowers in close, pendulous, subterminating aments: the females scattered, frequently two or three together: fruit an ovate, coriaceous, smooth drupe, inclosing an irregularly grooved nut, which contains a four-lobed, oily, eatable kernel, with an irregular knobbed surface, and covered with a yellow skin. It is a native of Persia.

Martyn remarks, that as "they all vary again

when raised from the seed, and that as nuts from the same tree will produce different fruit: persons who plant the Walnut for its fruit, should make choice of the trees in the nurseries, when they have their fruit upon them."

There are several varieties, as the Oval Walnut, the Round Walnut, the Large Walnut, the Small-fruited Walnut, the Double Walnut, the Early Walnut, the Late Walnut, the Tender Thin-shelled Walnut, and the Hard Thick-shelled Walnut.

The second species has the leaves composed of two or three pairs of oblong lobes, terminated by an odd one; these are of a light green, and serrate; the lower pair of lobes are the smallest, and the upper the largest: the fruit is shaped like the common Walnut, but the shell is not furrowed, and is of a light colour. According to some, it is a tall tree. In North America, where it prevails, it is termed Hickory Nut-tree.

The third grows to a large size: the leaves are composed of five or six pairs of leaflets, which end in acute points and are serrate; the lower pair is the least, the others gradually increase, but the pair at top and the terminating leaflet are smaller: these leaves when bruised emit a strong aromatic flavour, as does also the outer cover of the nuts, which is rough, and rounder than that of the first sort. The shell is very hard and thick, and the kernel small, but very sweet to the taste.

Culture.—All the sorts are capable of being increased by planting the seed or nuts, which in the first sort should be of the best varieties when intended as fruit trees, after they are become perfectly ripe, and have been preserved in dry sand till about the end of February, either in slight drills, five or six inches apart in the rows, and a foot distant, or by the dibble, at the same distances, putting them in to the depth of two or three inches, the ground having been previously well dug over. When the plants have had two years growth in the seed-bed, they should be removed into nursery rows, shortening the tap roots, but preserving the tops entire, putting them at the distance of two feet and a half from row to row, and a foot and half in the rows: they should remain in this situation till they have attained five or six feet in height, training them with single stems; after which they may be removed into the situations where they are to grow.

When the trees are intended for timber, it is a good practice to plant them out at once where they are to grow, as they thrive faster, and form better trees.

In raising the Walnut for fruit, Mr. Boucher, however, recommends flat stones, tiles, sherds, or slates, to be buried eight inches deep,

under the nuts when they are set: the distance to be six inches, and the depth two inches. After two seasons they should be removed early in autumn, and planted fourteen or sixteen inches asunder, on the same kind of bottom, or any hard rubbish, to prevent them from striking downwards, and to induce them to spread their roots on the surface. At the end of two or three years this should be repeated again, making the bedding at the depth of fifteen or sixteen inches, and planting them two feet asunder: here let them remain three or four years, when they will be fit to remove for the last time. The soil for fruit-trees should be dry and sound, with a sandy, gravelly, or chalky bottom. The trees managed in this way, he says, will have higher flavoured fruit, ripen earlier, and bear a plentiful crop twenty years sooner than in the usual method. The best manure for them is ashes, spread the beginning of winter, the land having been first ploughed or dug over.

And as plants raised from the nuts of the same tree bear fruit of very different qualities, he advises the inarching one of the best sorts on the common Walnut-tree; by which method the planter is secure of his sort, and will have fruit in one-third of the time that he would obtain it from the nut. This method can, however, be practicable only in few situations. The length of time in which the Walnut bears well from the nut is about twenty years.

The nuts of the two other sorts are procured from America by the nurserymen.

The first sort is cultivated for ornament, as well as the nut or fruit which it affords. The fruit is used in two different stages of its growth; as, when green, to pickle; and when ripe, to eat the kernel. For the first purpose, the young green Walnut, when about half or near three parts grown, before the outer coat and internal shell become hard, is most excellent; for which they are generally ready in July or the following month, and should be gathered by hand, chusing such as are as free from specks as possible.

The fruit is discovered to be fully ripe by the outer husk easily separating from the nut, or by the husks sometimes opening, and the nuts dropping out; it is usually about the latter end of September, which, in trees of considerable growth, is commonly beaten down with long poles; for, as the Walnuts grow mostly at the extremity of the branches, it would, in very large spreading trees, be troublesome and tedious work to gather them by hand. As soon as gathered, they should be laid in heaps a few days to heat and sweat, to cause their outer husks, which closely adhere, to separate from the shell of the nuts; then be cleaned from the rubbish,

and deposited in a dry room for use, covering them over close with dry straw, a foot thick, where they will keep three or four months. They are always ready sale at market, in large towns, where, at their first coming in, they are brought with their husks on, and sold by the sack, or bushel, but afterwards cleaned, and sold both by measure and the thousand.

Plantations of these trees are therefore profitable, in their annual crops of fruit, while growing, and in their timber, when felled or cut down.

These, as well as the other sorts, may many of them be admitted into clumps and plantations, in large pleasure-grounds, for variety. After one or two years the other sorts are nearly as hardy as the first; but till that time should be protected against frosts in the winter season.

JUNIPERUS, a genus containing plants of the evergreen tree and shrub kinds.

It belongs to the class and order *Dioecia Monadelphica*, and ranks in the natural order of *Coniferae*.

The characters are: that in the male the calyx is a conical ament, consisting of a common shaft, on which are disposed three opposite flowers in triple opposition; a tenth terminating the ament: each flower has for its base a broad, short, incumbent scale affixed to the column of the receptacle: there is no corolla: the stamina have filaments (in the terminal floscule) three, (four to eight), awl-shaped, united below into one body: (in the lateral flowers scarce manifest:) anthers three, distinct in the terminal flower, but fastened to the calycine scale, in the lateral ones: in the females the calyx is a three-parted perianthium, very small, growing to the germ, permanent: the corolla has three petals, permanent, rigid, acute: the pistillum is an inferior germ: styles three, simple: stigmas simple: the pericarpium is a fleshy berry, roundish, marked on the lower part with three opposite obscure tubercles (from the calyx having grown there), and at the tip by three teeth (which before were the petals), umbilicated: the seed three ossicles, convex on one side, cornered on the other, oblong.

The species cultivated are: 1. *J. communis*, Common Juniper; 2. *J. Oxycedrus*, Brown-berried Juniper; 3. *J. thurifera*, Spanish Juniper; 4. *J. Barbadensis*, Barbadoes Juniper; 5. *J. Bermudiana*, Bermudas Juniper; 6. *J. Sabina*, Savin; 7. *J. Virginiana*, Virginian Juniper, or Red Cedar; 8. *J. Phœnicea*, Phœnician Juniper, or Cedar; 9. *J. Lycia*, Lycian Juniper, or Cedar.

The first is a low shrub, seldom rising more than three feet high, sending out many spreading tough branches, which incline on every

side, covered with a smooth, brown, or reddish bark, with a tinge of purple: the leaves narrow, awl-shaped, ending in acute points, placed by threes round the branches, pointing outwards, bright green on one side, and gray on the other, continuing through the year: the male flowers are sometimes on the same plant with the females, but at a distance from them; but they are commonly on distinct plants: the female flowers are succeeded by roundish berries, which are first green, but when ripe of a dark purple colour, continuing on the bush two years. It is common in all the northern parts of Europe.

The second species has the branchlets three-sided: the leaves sessile (by no means adnate), altogether as in the first sort, but larger in all the parts: berries rufescent, the size of a hazelnut: the height ten or twelve feet, branched the whole length: branches small and taper, having no angles, as most of the other Junipers have: the male flowers at the ends of the branches in conical scaly aments: the berries below from the side of the same branch: it is feathered from top to bottom, if left untouched from the first planting, or if not crowded with other trees: the short sharp-pointed leaves give the shrub a fine look; and the large brownish red berries have a handsome appearance when ripe. It is a native of Spain.

The third grows to the height of twenty-five or thirty feet, and sends out many branches, which form a sort of pyramid: the leaves are acute, lying over each other in four rows, so as to make the branches four-cornered: the berries very large, and black when ripe. It is a native of Spain.

The fourth species has been confounded with the Bermudas Cedar; but the branches spread very wide, the leaves are extremely small, and are every where imbricate: the bark is rugged, splits off in strings, and is of a very dark colour: the berries are smaller than those of the Bermudas Cedar, and are of a light brown colour when ripe. It is a native of the West Indies, where it rises to be one of the largest timber trees.

The fifth, or Bermudas Cedar, whilst young, has acute-pointed leaves, which spread open, and are placed by threes round the branches; but as the trees advance their leaves alter, and the branches become four-cornered: the leaves are very short, and lie over each other by fours round the branches: the berries are produced towards the ends of the branches, and are of a dark red colour, inclining to purple: the wood has a very strong odour. It is a native of America.

The sixth is divided into two species by Mil-

ler; the Common, or Cypress-leaved, and the Tamarisk-leaved, or Berry-bearing Savin. In the first the branches grow more erect, the leaves are shorter, and end in acute points, which spread outwards: it rises to the height of seven or eight feet, and produces great quantities of berries. The second sends out its branches horizontally, and seldom rises more than three or four feet high, but spreads to a considerable distance every way: the leaves are very short, acute-pointed, running over each other along the branches, with the ends pointing upwards: the berries are smaller than those of the first, but of the same colour, and a little compressed: the whole plant has a very rank odour when handled. It is a native of the South of Europe.

There is a variety with variegated leaves.

The seventh has the leaves mutually opposite by threes, fastened at the base by their inner side, in the new shoots imbricate in four rows, giving them the appearance of being quadrangular; the year following these spread from the branch at an acute angle, and appear to be disposed in six rows or longitudinal phalanges: the berry dark blue, covered with a white resinous meal. It is a native of North America, &c.

There are varieties, as the Swedish, or Tree Juniper, which rises to the height of ten or twelve (even sixteen or eighteen) feet: the branches grow more erect than those of the common Juniper; the leaves are narrower, end in more acute points, and are placed further asunder on the branches: the berries also are longer.

The Alpine, or Mountain Juniper, which has the leaves broader and thicker: the berries rather oval than spherical.

The eighth species grows with its branches in a pyramid: the lower ones have short, acute-pointed, grayish leaves, pointing outwards; but those on the upper branches are dark-green and imbricate, ending, however, in acute points: the male flowers are produced at the extremity of the branches, in a loose, scaly, conical ament, standing erect on a short peduncle: the fruit is sometimes upon the same tree, at a distance from the male flowers, but more generally on separate trees: the berries pale yellow when ripe, about the size of those of the first sort. It is a native of the South of Europe.

The ninth has the branches growing erect, and covered with a reddish-brown bark: the leaves small, obtuse: the male flowers at the ends of the branches in a conical ament; and the fruit single from the axils below them, on the same branch: the berries large, oval, and when ripe brown. It is a native of the South of France.

Culture.—All these plants, except the fifth sort, may be increased either by seeds, layers, or cuttings. The latter methods are proper for the Savin kinds.

The seeds or berries should be sown in beds of light earth, in the early autumn or spring, but the former is the better in light soils, in a warm sheltered situation, in the open ground, being well raked in. The beds should be kept perfectly clear from weeds, and the young plants be occasionally watered during the summer season. When the plants have had two years' growth in these beds, and are become strong, they should be removed into nursery rows at two feet apart, and a foot or eighteen inches distant in the rows. They should remain in these situations till of proper growth to be planted out where they are to remain.

The layers of the young branches should be laid down at either of the above seasons, and, when well rooted taken off, and planted in the nursery, in the same manner as the seedling plants.

The cuttings should be made from the young branches, and be planted in a shady border, in the latter end of summer, watering them occasionally till they have stricken good root; when they may be taken up with earth about their roots, and be managed in the same manner as by the other methods.

The plants raised in these last ways seldom grow so upright, or to so large a size, as in the seed method.

The common upright and striped Savins may likewise be increased by planting slips of the young branches; for the last sort the most variegated being made use of, in the latter end of summer, or in the autumn, in a shaded border, due water being given. When the plants are come up, they must be managed as the other sorts.

The fifth sort must be sown in pots or tubs, at the same seasons as the other sorts, being placed in a frame to have the protection of glasses when the weather is frosty and severe. As the seeds are long in coming up, the mould in the pots, &c. must remain undisturbed till they appear, being shaded from the sun, and slightly watered occasionally. The young plants should be kept quite free from weeds, and be duly watered till they have attained sufficient growth to be removed into separate small pots, filled with light earth, which is generally when from one to two years old. In removing them, they should have balls of earth preserved about their roots, and be watered, and placed in a warm situation. The best season for this is in the early spring. But it is of great advantage to plunge the pots in a mild hot-bed. They

must be protected in the winter, either in frames, or under a warm fence, the pots being plunged in the earth. When they have been removed into different larger pots till of sufficient large growth, they may be planted out where they are to grow, which should be in a warm situation. It is proper to shelter them the first two winters during severe frosts, by mats, or other similar coverings.

The proper periods for removing all the different sorts into the open ground, are in the early autumn or spring months.

These plants all succeed in the open ground, and grow in any common soil and situation, with other hardy plants of the tree kind, though they are the most prosperous in a light sandy soil, where the aspect is sheltered.

In placing these kinds of plants in the clumps and shrubby plantations, attention should be had to arrange them according to their degrees of growth, so as to exhibit a regular gradation of height, placing the low-growing sorts, as the common Juniper and Savin kinds, towards the fronts, and the other larger growing sorts more backwards, in assemblage with other ornamental shrubs and trees of the evergreen tribe; and some may be placed as single standards, on open spaces of short grass, in the pleasure-ground quarters. Some of the large-growing sorts may also be introduced into the forest-tree plantations; as they have a fine effect, and afford excellent timber for many uses, more particularly the Virginia Cedar, which arrives at a considerable size, especially when the under branches are trimmed off occasionally while young.

JUPITER'S BEARD. See *ANTHYLLIS*.

JUSTICIA, a genus containing plants of the shrubby and herbaceous kinds.

It belongs to the class and order *Diandria Monogynia*, and ranks in the natural order of *Personateæ*.

The characters are: that the calyx is a one-leaved perianthium, very small, five-parted, acute, upright, narrow: the corolla one-petalled, ringent: tube gibbose: border two-lipped: lip superior oblong, emarginate: lip inferior, of the same length, reflex, trifid: the stamina have two awl-shaped filaments, hid under the upper lip: anthers upright, bifid at the base: the pistillum is a top-shaped germ: style filiform, length and situation of the stamens: stigma simple: the pericarpium is an oblong capsule, obtuse, narrowed at the base, two-celled, two-valved: the partition opposite to the valves, gaping with an elastic claw: the seeds roundish.

The species cultivated are: 1. *J. sexangularis*,

E

Chickweed-leaved *Justicia*; 2. *J. Scorpioides*, Scorpion-tail Vera Cruz *Justicia*; 3. *J. Ectolium*, Long-spiked *Justicia*; 4. *J. Adhatoda*, Malabar Nut; 5. *J. hyssopifolia*, Snap-tree.

The first is an annual plant, with an upright stalk, having six angles, rising two or three feet high, and dividing into many branches: the leaves opposite, an inch and half long, and one inch broad; smooth, as are also the stalks: at each joint come out clusters of small bractes: long before the stalks decay, most of the leaves fall off, leaving only these bractes: the flowers are in small spikes at the side of the branches, sitting very close; they are of a beautiful carmine colour. It is a native of La Vera Cruz, &c.

The second species has a brittle stem, five or six feet high, sending out many branches: the leaves two inches long, and one inch broad, hairy, opposite: the flowers large, of a carmine colour, and ranged on one side of the spike. It is a native of La Vera Cruz.

The third has a roundish stem, compressed, jointed: the leaves petioled, smooth, acuminate, quite entire: the spike strobile-shaped, with spreading, upright bractes: it grows five feet high: the flowers grow in very long spikes from the end of the branches, and are of a greenish colour, with a shade of blue. It is a native of the East Indies.

The fourth species rises here with a strong woody stem to the height of twelve or fourteen feet, sending out many spreading branches: the leaves more than six inches long, and three inches broad, placed opposite: the flowers on short spikes at the end of the branches. It flowers in July, and is a native of Ceylon.

The fifth has the stem from three to four feet high, sending out branches on every side from the bottom, so as to form a pyramid; they are covered with a white bark: the leaves entire, near two inches long, and one third of an inch broad, smooth, stiff, deep green, opposite: at the base of the foot-stalks come out clusters of smaller leaves, of the same shape and texture: the peduncles short: the flowers white, with long calyxes: the capsules oblong, when ripe throwing out their seeds, whence the name of Snap-tree. It is a native of the Canary islands.

Culture.—These plants may be increased, some of them by seeds, and the others by layers and cuttings; but the latter modes are mostly practised, as the seeds are obtained with difficulty.

Where the seeds are capable of being procured, they may be sown in small pots filled with light fresh earth, in the early spring, being plunged in a hot-bed of bark, watering the

mould of the pots moderately when it becomes dry. As they often remain long before the plants appear, the pots should not be disturbed, but be kept in the hot-bed. When the plants appear, fresh air should be admitted in mild weather, and slight waterings given; and when they have attained a few inches in growth, they should be removed into separate pots filled with fresh earth, replunging them in the hot-bed, watering and shading them till they have taken fresh root; air being then freely admitted, and as the season grows warm, due waterings being given. As they advance in growth, they should be placed in larger pots, taking care not to overpot them, keeping them constantly in the hot-bed.

The layers should be laid down in the early spring, in pots filled with light earth, a little water being given at the time.

The cuttings may be made from the young shoots, and planted in pots filled with the same sort of earth in the later spring or summer months, giving them a little water, and plunging them in the hot-bed of bark in the stove, due shade being given.

When the plants have become perfectly rooted, they may be taken off, or removed into separate pots, keeping them constantly in the stove or green-house, according as they are more or less hardy. The two first sorts are the most hardy; the others succeeding best in the hot-house or stove.

The two first afford ornament and variety among the other potted plants of the less tender sorts, and the other among those of the stove kinds.

IVY. See *HEDERA*.

IXIA, a genus containing plants of the herbaceous, bulbous, and tuberous root perennial kind.

It belongs to the class and order *Triandria Monogynia*, and ranks in the natural order of *Ensateæ*.

The characters are: that the calyx is a spathe, bivalve, inferior, shorter than the corolla: valves oblong, permanent, the exterior wider, sheathing the interior: the corolla one-petalled, regular, superior: tube filiform, gradually enlarged, straight: border regular, bell-shaped, six-parted: divisions oblong, obtuse, equal, spreading: the stamina have three filaments, thread-subulate, inserted into the tube near the orifice, shorter than the corolla: anthers oblong, furrowed: the pistillum is an inferior, triangular germ: style simple, filiform, upright: stigma three, filiform: the pericarpium is an ovate capsule, three-sided, obtuse, three-celled, three-valved: the seeds several, roundish, smooth.

Ixia chinensis
1 Chinese Ixia

Iberis gibraltarica
2 Gibraltar Candy Tuft

The species cultivated are: 1. *I. Bullocodium*, Crocus-leaved Ixia; 2. *I. Chinensis*, Chinese Ixia; 3. *I. rosea*, Rose-coloured Ixia; 4. *I. bulbifera*, Bulb-bearing Ixia; 5. *I. aristata*, Bearded Ixia; 6. *I. flexuosa*, Bending-stalked Ixia; 7. *I. polystachia*, Many-spiked Ixia; 8. *I. maculata*, Spotted Ixia; 9. *I. crocata*, Crocus-flowered Ixia.

The first has a roundish bulb, placed on the withered bulb, double the size of a pea, white, covered with a bay-coloured skin: the leaves three or four, in the flowering plant radical, in the fruiting cauline, spreading horizontally, half a foot or thereabouts in length, smooth, sharpish: the stem solitary, upright, two inches high, above the uppermost leaf, convex on one side, flat on the other; in the fruiting plant a little higher, in the cultivated one sometimes half a foot in height: the spathe terminating, two-valved: leaflets narrow-lanceolate, acute, concave, opposite; one upright, green, almost the length of the corolla; the other a little shorter, green on the back, but otherwise membranaceous and pellucid, patulous, whence the flower becomes as it were lateral. It is inodorous, and a native of Italy, flowering about the middle of April.

It varies with white and yellow flowers, with purplish and yellow flowers, with blue and white flowers, with white flowers, and with variegated flowers.

The second species has the scape round, fistulous, jointed, upright, simple at bottom, panicle-dichotomous or trichotomous at top, smooth, almost the thickness of a finger, two feet high: the leaves alternate, embracing, equitant, acute, entire, striated, smooth, the lower a little longer, about half the length of the stem, a span long and more: the flowers from the tips of the branches of the panicle, in umbels, from three to seven, peduncled: peduncles striated, one-flowered, an inch long: the spathe under the divisions and the umbel, withered. In India, the stalks rise to the height of five or six feet, but in this climate they are seldom more than half that height. The flowers are of a yellow colour within, and variegated with dark red spots; the outside is of an orange colour: these appear in July and August, and in warm seasons are succeeded by seeds. It is a native of the East Indies, &c.

The third has an ovate bulb, smooth, sub-truncated: the scape three- (or four-) cornered, sheathed at bottom, branched, few-flowered, smooth, from a hand to a span in height: the leaves acute, grooved, smooth, the lowest, which is the longest, frequently double the length of the scape, or more, is lax and reflex;

the two or three others are about the length of the scape, and upright: the flowers at the ends of the branches rather large, coming out one after the other: the outer spathe ovate, green; inner lanceolate, acute, membranaceous, sheathing the capsule.

It varies with the three inner segments of the corolla yellow, and the three outer green; with the three inner white-yellow, the three outer greenish; with the three inner blue-white, the three outer greenish; with the three inner white, the three outer green; with corollas wholly yellow; or wholly blue, or rose-coloured with a yellow base; also in the size of the flowers.

The fourth species has the scape simple or branched, somewhat compressed, striated, smooth, sheathed at bottom with leaves, from a hand to a foot in height: the leaves nerved and striated, distich, upright, smooth, a span long: the flowers three or more, large, with the rachis between the flowers flexuose: the spathe nerved and netted, gray, with a dusky tip: tube of the corolla only a line in length: border divided beyond the middle, but not to the tube: segments large, ovate-oblong, very blunt, spreading.

It varies with the corolla purple, red and white, yellow; with the scape very short and simple, higher and branched, and bulbiferous.

The fifth has a netted bulb, the size of a hazel nut: the scape simple, round, upright, smooth, from a hand to a foot in height and more: the leaves four or five, linear, five-nerved, the middle nerve and edges thicker, acute, upright, shorter by half than the scape: the flowers pointing one way (very seldom one only) on two branches, often from five to nine on a scarcely flexuose rachis: the spathes submembranaceous, awn-toothed: the corollas white flesh-coloured.

It varies with the segments of the borders of the corolla of a deep and elegant purple-violet colour within, three of them of the same colour on the outside, but the three others alternately of a pale dirty violet; one of these with two on the side of it has a double band in the throat meeting at one end; and, according to Mr. Salisbury, with whitish corollas, having a purple star, violet-coloured and yellow. In Miller's figures, with the corolla of a beautiful purple on the outside, but white within, and the stem terminated by two or three flowers; with the stalk terminated by two large flowers; the outside of a violet colour, edged with white, and the inside pale blue; and with one flower, and the corolla of a most beautiful purple colour both within and without.

The sixth species has a very small round bulb: the leaves three or four, long, slender, grass-

like, dark green: the stem very slender, round, a foot and half high: at the top the flowers are collected in a spike sitting close to the stalk, each having a thin, dry spathe, which covers the capsule after the flower is fallen. The corolla is pure white, and small.

The seventh species has a bulb the size of a hazel nut: the leaves three or four, many-nerved, upright, smooth, half the length of the scape: the scape round, smooth, upright, many-spiked, from a foot to two feet in height: the branches alternate, capillary, upright, a finger's length: the flowers on the scape and branches in spikes, on a flexuose rachis of a finger's length: the spathes submembranaceous and awned. The flowers appear in May.

It varies with the corollas yellow and violet, of one colour.

The eighth species has the bulb double the size of a hazel nut: the leaves three, four, or five, many-nerved, half the length of the scape: the scape usually simple, seldom many-spiked, round, upright, from a span to a foot high and more: branches filiform, upright, or spreading very much: flowers in terminating spikes, on a flexuose rachis: spathes membranaceous, gray at the base, brown at the tip, somewhat jagged: the corolla, above the mouth of the tube, has a dusky spot at the base of the border.

According to Miller, the stalk is slender, stiff, a foot and half long, naked to the top, where it is terminated by a round bunch of flowers, each inclosed in an oblong spathe, which is permanent, and splits open on one side: the flowers are on short peduncles, deep yellow with a dark-purple bottom. It flowers in May and June.

The ninth has the bulb a little larger than a hazel nut: the leaves about five, reflex-subfalcate, many-nerved, from an inch to a finger's length, half or one-third of the length of the scape: the scape simple, round, or branched, somewhat flattened, flexuose, upright, smooth, from a hand to a span in height: the branches spreading very much, naked, like the scape: the bractes gray at the base, ferruginous at the tip, slightly toothed and jagged: the flowers pointing one way, handsome, bell-shaped, with a short tube, orange-coloured with a paler hyaline or transparent mark above the mouth of the tube; seldom two, but most commonly five or seven. It is one of the handsomest of the *Ixias*, and like other sorts becomes handsomer and more branched by cultivation.

It varies with a short, simple, few-flowered scape, and a dark spot above the windowed or hyaline one, with a lofty, many-spiked, many-flowered scape, and with bright red flowers.

Culture.—These plants may be increased by seeds or off-sets.

The seeds of such sorts as can be procured should be sown in pots filled with light earth, in the spring, plunging them in a mild hot-bed. When the plants have attained some growth, they should be removed into separate pots of the same earth, being placed under the protection of a frame till they have taken root. They should be placed during the winter in a hot-bed frame. They may afterwards be removed into warm borders, being protected from frosts in the winter, and a few retained in pots under the frame, or in a dry stove.

They are three or four years in flowering when raised from seeds.

The common way is therefore to increase them by planting off-sets from the roots, which are afforded in great plenty; the proper season for this is in the early spring, before the shooting of the root, when the roots should be removed, and the off-sets taken off and planted out.

The old roots should not be removed oftener than every three years.

When the stems and leaves decay to the roots in the borders in autumn, they should be covered over with tan a few inches thick, to protect them from frost and the depredations of mice.

The hardy sorts serve to adorn the borders in the open ground, and the other tender sorts among other potted green-house plants, that require protection in winter.

IXORA, a genus containing plants of the flowering shrubby exotic kind.

It belongs to the class and order *Terrandria Monogynia*, and ranks in the natural order of *Stellatæ*.

The characters are: that the calyx is a four-parted perianthium, very small, upright, permanent: the corolla one-petalled, funnel-form: tube cylindric, very long, slender: border four-parted, flat: divisions ovate: the stamina have four filaments, above the mouth of the corolla, very short: anthers oblong: the pistillum is a roundish, inferior, germ: style filiform, length of the tube: stigma two-cleft: the pericarpium a roundish berry, two-celled: the seeds by fours, convex on one side, cornered on the other.

The species cultivated are: 1. *I. coccinea*, Scarlet *Ixora*; 2. *I. alba*, White *Ixora*.

The first has a woody stem, five or six feet high, sending out many slender branches covered with a brown bark: the leaves opposite, or three or four at a joint: the flowers terminating in clusters; they have very long slender tubes, are cut into four ovate segments, and are of a deep red colour. It is a native of the East Indies.

The second species has a woody stem, six or seven feet high, sending out weak branches: the leaves are opposite, sessile: the flowers terminating in small clusters; they have long slender tubes, divided into four segments at top, and are white, without scent. It is a native of the East Indies.

Culture.—These plants may be increased by seeds, when they can be procured from the countries where they grow naturally, as they do not perfect them in this climate. They should be sown in small pots as soon as they arrive, and be plunged into a hot-bed, when they arrive in autumn or winter seasons, the pots being plunged in the tan-bed in the stove; but when they come in the spring, it is best to plunge them in a tan-bed under frames. The seeds sometimes come up in about six weeks, if they are quite fresh; otherwise they lie in the ground four or five months,

or longer. The earth should therefore not be thrown out of the pots till there are no hopes of their growing. When the plants come up, and are fit to remove, they should be each planted in a separate small pot, filled with light earth, being preserved in the green-house or stove.

They may also be increased by cuttings, which should be planted during the summer months, in small pots, and plunged into a moderate hot-bed, covering them close either with bell or hand glasses, to exclude the external air, shading them carefully from the sun in the heat of the day until they have put out good roots, when they should be parted, and each put into a separate pot, treating them as the seedling plants. Mr. Curtis thinks it probable, that these plants are less tender than is supposed.

They afford variety among other stove or green-house plants.

K Æ M

KADANAKU. See ALOE.

KÆMPFERIA, a genus containing plants of the herbaceous perennial flowery kind.

It belongs to the class and order *Monandria Monogynia*, and ranks in the natural order of *Scitamineæ*.

The characters are: that the calyx is a superior perianthium, obscure: the corolla is one-petalled: tube long, slender: border flat, six-parted: the three alternate divisions lanceolate, equal: the other two divisions ovate; the upper one two-parted: the divisions obcordate: all equal in length: the stamina have one membranaceous filament, subovate, emarginate: anther linear, doubled, entirely adnate, scarce emerging from the tube of the corolla: the pistillum is a roundish germ: style the length of the tube: stigma two-plated, roundish: the pericarpium is a roundish capsule, three-sided, three-celled, three-valved: the seeds are several.

The species cultivated are: 1. *K. Galanga*, Galangale; 2. *K. rotunda*, Round Kæmpferia.

The first is an annual, stemless, juicy plant: the root is bulbous, palmate, creeping, with ovate smooth lobes, and awl-shaped thick simple fibres: the leaves are broad-ovate, forming a ring next the ground, quite entire, smooth, with many longitudinal grooves, dark green, on short membranaceous, subterraneous petioles, embracing

K Æ M

the inner ones: the flower radical, solitary, sessile, juicy, very white, with a large violet spot in the middle. It is a native of the East Indies.

The second has the roots somewhat like those of the first, but shorter, growing in large clusters, covered with an ash-coloured skin, but within white: from the roots arise the leaves, which fold over each other at their base: they are six or eight inches long, and three broad in the middle, gradually ending in acute points; the flowers arise immediately from the roots, each having a spatha at bottom cut into two segments, which closely embrace the foot-stalk: they have six petals, the three lower which decline downward are long and narrow, the two upper are divided so deeply as to appear like a flower with four petals, and the side petal is bifid: they are of mixed colours, blue, purple, white, and red, having a fragrant odour. It flowers in July and August, and is a native of the East Indies.

Culture.—These plants are increased by parting the roots, and planting them out in the spring, before they send forth new leaves, in pots of light rich mould; keeping them in the hot-house, giving water plentifully in the summer, but sparingly in the winter season.

They afford variety in stove collections.

KALE. See **BRASSICA**.

KALMIA, a genus containing plants of the hardy evergreen shrubby kind.

It belongs to the class and order *Decandria Monogynia*, and ranks in the natural order of *Bicornes*.

The characters are: that the calyx is a five-parted perianthium, small, permanent: segments subovate, acute, rather columnar: the corolla one-petalled, salver-funnel-form: tubecylindric, longer than the calyx: border with a flat disk; the margin upright, half-five-cleft: ten nectariferous hornlets projecting outwardly from the corolla, and surrounding it where the border of it is upright: the stamina have ten awl-shaped filaments, upright-spreading, rather shorter than the corolla, inserted into the base of the corolla: anthers simple: the pistillum is a roundish germ: style thread-form, longer than the corolla, bent down: stigma obtuse: the pericarpium a capsule, subglobose, depressed, five-celled, five-valved, five-partite: the seed numerous.

The species cultivated are: 1. *K. latifolia*, Broad-leaved Kalmia; 2. *K. angustifolia*, Narrow-leaved Kalmia; 3. *K. glauca*, Glaucous Kalmia; 4. *K. hirsuta*, Hairy Kalmia.

The first rises with a branching stalk to the height of ten or twelve feet, with very stiff leaves, which are two inches long and one broad, of a lucid green on their upper side, but of a pale green on their under: they have short foot-stalks, and stand without order round the branches: between these the buds are formed for the next year's flowers, at the extremity of the branches; these buds swell during the autumn and spring months, till the beginning of June, when the flowers burst out from their empalements, forming a round bunch, or corymbus, sitting very close to the branch: they are of a pale blush colour, the outside of the petal a peach colour. In its native soil it continues flowering a great part of the summer, and is highly ornamental. It is a native of Carolina.

The noxious qualities of this elegant shrub lessen its value.

The second species rises from three to six feet high, dividing into small woody branches, which are very close, and covered with a dark-gray bark: the leaves are stiff, about two inches long, and half an inch broad, of a lucid green, placed without order upon the branches, on slender foot-stalks: the flowers are in loose bunches on the side of the branches, upon slender peduncles: they are bright red when they first open, but afterwards fade to a blush or peach-bloom colour.

There are varieties, with pale and deep-red flowers, differing in their habit: the latter, the

most humble of the two, not only produces the most brilliant flowers, but in greater abundance. It is reputed poisonous to sheep and cattle in North America, where it is a native.

The third is much inferior in size to the first, rarely exceeding two feet in height. It is a native of Newfoundland, flowering in April and May.

The fourth species is usually in height from two to three feet, growing upright: the flowers are about the same size with those of the preceding, are of a purple colour, and grow in racemes: the stalk, leaves, and calyx are covered with strong hairs. It is a native of Carolina.

Culture.—These plants are increased by seeds, layers, and suckers.

The first sort is mostly raised from seeds procured from America, which should be sown in pots or boxes of light sandy mould, in the spring, plunging them in an easterly border, or in beds of light mould in the same aspect. When placed on a gentle hot-bed they succeed better. They must, however, be inured to the full air in summer, being sheltered during the winter from frost. When the plants have had two years' growth, they may be removed into separate pots, to be continued two or more years, when they may be planted out in the open ground in warm situations.

The second sort is mostly increased by layers, which should be made from the young shoots, and laid down in the early autumn. When they are well rooted, in a year or two, they may be taken off, and planted in pots separately filled with bog earth, or in a warm border of the same sort of earth. This is more hardy than the former.

The third sort is increased in the same way as the first, and requires similar management.

The fourth is preserved with difficulty in this climate, but may be raised by layers.

The most of the plants may likewise be increased by suckers, which should be taken off and planted in the spring, in nursery rows, for two or three years, when they may be removed to the places where they are to grow.

These plants, in the more hardy sorts, afford ornament and variety in the fronts of shrubbery borders and clumps; and in the more tender sorts, among other potted green-house plants.

KIDNEY-BEAN. See **PHASEOLUS**.

KIDNEY-BEAN TREE. See **GLYCINE**.

KIDNEY-VETCH. See **ANTHYLLIS**.

KIGGELARIA, a genus containing a plant of the evergreen shrubby kind.

It belongs to the class and order *Diœcia Decandria*, and ranks in the natural order of *Columniferae*.

The characters are: that in the male the calyx

Painted by Syd Edwards

London Published Jan 11806 by G. Kearsley Fleet Street

Engraved by F. Sanson

1 *Kalmia glauca*
 1 *Glaucous Kalmia*

2 *Linum arboreum*
 2 *Tree Flax*

is a one-leaved perianthium, five-parted, concave: divisions lanceolate, concave: the corolla has five lanceolate petals, concave, rather longer than the calyx, and forming with it a pitcher-shaped figure: nectary, glandules obtusely three-lobed; middle lobe largest, depressed, coloured, each growing to the claw of each petal: the stamina have ten filaments, very small: anthers oblong, shorter than the calyx, gaping at the tips with two holes: female, the calyx as in the male: the corolla as in the male: the pistillum is a roundish germ: styles five, simple: stigmas obtuse: the pericarpium is a leathery, globose capsule, rough, one-celled, five-valved: the seeds about eight, roundish, cornered on one side, covered by a proper coat.

The species cultivated is *K. Africana*, African Kiggelaria.

It is a tree exceeding the height of a man, with the trunk and branches gray: the leaves are alternate, lanceolate, petioled, smooth, stiff, and straight, sharply serrate, acute, spreading: the petioles roundish, without stipules, one eighth of the length of the leaves: at the back of the leaf, where the larger lateral vessels come out, in the sinus or axil, there is a slight pubescence with a cavity, which forms a prominence on the upper surface of the leaf. On the male plant, one or two branched peduncles bear several flowers, nodding, in a panicle; the petals are white, and the nectaries yellow. The female produces a single flower on a simple peduncle: the fruit is a globular, rugged, one-celled, berried capsule, with a thick coriaceous rind, pubescent on the outside, and rugged, with granular atoms. It grows naturally at the Cape of Good Hope, where it rises to be a tree of middling stature; but it does not grow to a great magnitude in this climate.

KITCHEN-GARDEN PLANTS, all such plants as are cultivated for the purpose of food.

NAMES AND SORTS.

Agaricus campestris, the field agaric or mushroom.

Allium, garlick, onion, leek, &c. Of the first kind, large white garlick—red garlick.

In the second, or romambole.

In the third or onion, common oval Strassburgh onion—great oval Portugal onion—flat white Spanish onion—flat red Spanish onion—silver-skinned onion—bulbless-rooted Welch onion.

In the fourth, chives, or cives.

In the fifth, escalot, or shallot.

In the sixth, or Canada tree-onion.

In the seventh, or the leek, broad-leaved London leek—narrow-leaved leek.

Culture.—The plants may be increased by seeds, layers, and cuttings; but the first is the best method, as they root sparingly by layers and cuttings.

The seeds should be sown in the early autumn, in pots filled with fresh loamy earth, plunging them in a hot-bed. When they have a few inches growth, they should be removed into separate small pots, replunging them in the hot-bed; and when well rooted they should be gradually hardened to the open air.

The layers should be made from the young shoots of the same year, laying them down in the summer.

The cuttings of the young shoots should be planted in the spring, immediately before the plants begin to shoot, in pots filled with soft loamy earth, being plunged in a very moderate hot-bed, and covered with glasses, to exclude the air; due shade being afforded, and little water given after the first planting. Such as strike root may be removed into separate small pots of loamy earth, and be exposed to the air in a warm sheltered situation, till the autumn, when they should be placed under the protection of the green-house, and managed in the same way as trees of the Orange kind.

They afford variety among potted plants of the green-house kind.

KING'S SPEAR. See ASPHODELUS.

KITCHEN-GARDEN, that sort of Garden which is principally destined to the growth of different sorts of culinary vegetables and roots.

The land designed for this sort of garden should be sufficiently spacious, of a good depth and quality of mould, dry, and at the same time well situated for warmth, and the influence of the sun. See GARDEN.

MODES OF CULTURE.

By the spawn of the root, or invisible seed, running in lumps of earth or dung, in the autumn.

By the cloves of the root.

By the root and bulbs from the stalk.

By seed annually, which should be sown at different times in the early spring months.

By dividing the roots, and planting them out in spring.

By offsets of the root, planted out in spring.

By offset bulbs of the root, and the bulbs at top of the stalk, planted out in spring.

By seed annually, which should be sown in the early spring.

NAMES AND SORTS.

Anethum, dill, &c., common dill.
Fennel—light-green-leaved—dark-green fennel—sweet-seeded fennel.

Italian fennel.

Angelica savita, common angelica.

Apium, parsley, celery, &c., parsley—common plane-leaved parsley—curled-leaved common parsley—broad-leaved, or large-rooted parsley.

Celery—common upright celery—upright celery with solid stalks—turnip-rooted spreading celery.

Asparagus officinalis, common asparagus.

Atriplex hortensis, garden orach—white-leaved garden orach—green orach—purple orach.

Beta vulgaris, beet—common culinary beet—green-leaved culinary beet—white beet—chard, or great white Swiss beet—mangel wurzel beet.

Red beet—large, long red-rooted beet—turnip-rooted red beet—red-rooted beet with green leaves—pale-red beet.

Borago, borage.

Brassica, the cabbage, cauliflower, broccoli, turnip, &c., the cabbage—small early summer cabbage—dwarf early sugar-loaf-shaped cabbage—large, hollow, sugar-loaf cabbage—early Russia cabbage—common round white cabbage—long-sided hollow cabbage—oval hollow cabbage—flat-topped cabbage—musk-scented cabbage—giant cabbage—red cabbage.

Savoy cabbage—common green curled Savoy—large green Dutch Savoy—yellow Savoy.

Laciniated, and other open-leaved cole—green curled borecole—red curled borecole—thick-leaved curled borecole—finely fringed borecole—broad, erect, curled-leaved Siberian borecole, or Scotch cole, or kale, red and green—common plane-leaved green colewort.

Turnip cabbage—turnip cabbage with the turnip above ground—with the turnip under ground.

The cauliflower—early cauliflower—late cauliflower.

Italian *brassica*, or broccoli—early purple broccoli—late large purple broccoli, comprehending varieties, with blue, brown, green, and yellowish heads—dwarf purple broccoli—white or cauliflower-broccoli—black broccoli.

The turnip—early Dutch turnip—white round turnip—green-topped turnip—red-topped turnip—yellow turnip—oblong white turnip—long white-rooted French turnip—round purple French turnip.

Calendula officinalis, common marigold.

Cichorium endivia, endive—green curled endive—white curled endive—broad-leaved Batavian endive.

MODES OF CULTURE.

- By seed annually, sown in the spring.
- By seed sown in spring; also by slipping the old roots, and planting them out in the autumn.
- By seed annually, sown in the spring.
- By seed annually, sown in spring.
- By seed sown in spring.

By seed sown in the spring, for transplanting in summer and autumn.

By seed sown in the autumn; and when once raised, the roots abide for some years.

By seed annually, sown in the spring.

By seed annually, sown in the spring months.

By seed annually, sown in the early spring.

By seed annually, sown in autumn or spring.

By seed annually, sown at different times in spring and autumn, for use all the year, by having the plants set out at various times.

By seed annually, sown in spring, for autumn and winter use.

By seed annually, sown in spring and summer, for plants for autumn and winter use.

By seed, sown annually in spring and summer.

By seed sown annually, in spring and autumn, for plants for summer and autumn use.

By seed, sown in spring and beginning of summer, for plants for autumn, winter, and spring use.

By seed sown in spring and summer, for plants for use most part of the year.

By seed sown annually, in spring, summer, or autumn.

By seed sown annually, in summer, from May till July, for plants for autumn and winter use.

NAMES AND SORTS.

Cochlearia armoracia, horse-radish.

Crambe, sea-cabbage or colewort—the different varieties.

Cucumis, cucumber and melon—the cucumber—early short prickly cucumber—early cluster-cucumber—long, green, prickly cucumber—long, white, prickly cucumber—long, smooth, green, Turkey cucumber—large, smooth, white cucumber—large, smooth, green, Roman cucumber.

The melon—Romana melon—Cantaleupe melon; varieties of each; and several other sorts.

Cucurbita, the gourd and water melon.

Cynara, artichoke and cardoon—the common artichoke—globular-headed, red Dutch artichoke—oval-headed, green French artichoke.

The common cardoon.

Daucus carota, the carrot—orange-coloured carrot—red carrot—yellow carrot—white carrot.

Helianthus tuberosus, tuberous sun-flower, or Jerusalem artichoke.

Hyssopus officinalis, common hyssop—the several different varieties.

Lactuca, lettuce—early green cabbage-lettuce—white cabbage-lettuce—brown Dutch cabbage-lettuce—great admirable cabbage-lettuce—green and white ball-cabbage-lettuce—green cos-lettuce—white cos-lettuce—black cos-lettuce—spotted Aleppo cos-lettuce—brown Cilicia lettuce—imperial lettuce—red capuchin lettuce—green capuchin lettuce—curled lettuce.

Lavandula, lavender—spike-flowered common lavender—common narrow-leaved—broad-leaved—blue-flowered—white-flowered—and dwarf lavender.

Stoechas, or French lavender.

Lepidium sativum, garden-cress—common small-leaved—broad-leaved—curled-leaved.

Melissa officinalis, balm—common balm.

Mentha, mint, penny-royal, &c. green common spearmint—curled-leaved spearmint—variegated spearmint.

Peppermint.

Penny-royal.

Ocimum Basilicum, basil—common sweet basil—several varieties.

Origanum, marjoram—common, wild, perennial pot marjoram—winter perennial sweet-marjoram—marjorana, or annual sweet-marjoram.

Vol. II.

MODES OF CULTURE.

By pieces of the roots planted out in spring, for use most part of the year.

By seed sown in spring; but when once raised, the roots remain for years, sending up shoots for use in spring and summer.

By seed sown annually, at different times, on hot-beds, in the early spring and summer.

By seed sown annually, at different times, on hot-beds, in the spring months.

By seed sown annually, in the spring season.

By suckers from the sides of the old plants, in spring, of many years' duration.

By seeds sown annually, in the early spring.

By seed sown annually, in spring, summer, and autumn, for use most part of the year.

By pieces of the root planted annually, in the spring season.

By seed sown in spring, and by planting slips and cuttings of its branches.

By seed sown annually, at different times, in spring, summer, and autumn, for plants for setting out for use most part of the year.

By slips planted out in spring, which are of many years' continuance.

By planting slips or cuttings, and by seed, which are of many years' duration.

By sowing seed at different times of the year, according as the plants are wanted.

By dividing and planting the roots in spring or autumn, which are of many years' duration.

By dividing the roots, by young plants, and by cuttings of the stalks, planted out in spring, and which continue many years.

By roots and plants, &c. like the former.

By dividing and slipping the plants, as for the mint, and planting them out.

By seed sown in spring, on a hot-bed, the plants being afterwards planted out.

By sowing seeds in spring, and the two former also by slipping the roots, and planting them.

NAMES AND SORTS.

Pastinaca sativa, parsnep—common garden parsnep.

Phaseolus vulgaris, common kidney-bean—dwarfs and runners. Dwarf kinds—early white—early yellow—liver-coloured—speckled dwarf—Canterbury white dwarf—Battersea white dwarf—large white dwarf—cream-coloured dwarf—black dwarf—sparrow-egg dwarf—amber-speckled dwarf.

Running kinds—scarlet runner—white variety—large Dutch runner—Battersea white runner—negro runner—variable runner.

Pisum, the pea—Charlton pea—golden Charlton—earliest golden Charlton—long Reading hotspur—Masters' hotspur—Spanish morotto—green nonpareil—early dwarf marrowfat—large marrowfat—green rouncival, or union—white rouncival—Ledman's dwarf pea—small sugar pea—large sugar pea—cluster pea—crown pea—egg-pea—sickle pea, &c.

Portulaca oleracea, purslane—green purslane—golden purslane.

Poterium Sanguisorba, burnet—common garden burnet.

Raphanus sativus, the radish—short-topped early radish—long-topped radish—deep-red radish—pale-red, transparent, mild radish—salmon-coloured radish—small white turnip-rooted radish—small red turnip radish—large, white, turnip-rooted Spanish radish—large, black, turnip-rooted Spanish radish.

Rosmarinus, rosemary—some varieties.

Rumex acetosa, sorrel—common long-leaved sorrel—round-leaved French sorrel—barren sorrel.

Ruta graveolens, rue; several varieties.

Salvia, sage, clary, &c. The sorts are—common sage—red sage—broad-leaved green sage—narrow-leaved green sage—broad-leaved hoary sage—sage of virtue—wormwood sage, &c.

Clary.

Satureja, savory—winter perennial savory—summer annual savory.

Scandix Cerefolium, chervil—annual garden chervil.

Scorzonera, scorzonera—Spanish scorzonera.

Sinapis, mustard—white mustard—black mustard—field or wild mustard; the former to use young in salad, and the two last for their seeds, to make the table sauce called mustard.

Sium sisarum, sisarum or skirret.

Smyrnum Olusatrum, Alisanders, or common Alexanders.

MODES OF CULTURE.

By seed sown annually, in spring, for winter use.

By seed sown annually, at different times from April till July or the following month.

By sowing the seed like the former, but principally in the summer months.

By seed sown annually, at different times from October till June, but principally in the early spring months.

By seed sown at different times in April and May.

By seed sown in autumn or spring, and parting the roots.

By seed sown at different times from Christmas till July or August; but the latter sorts sown principally in June and July, for autumn and winter use.

By planting layers, slips, and cuttings, in spring.

By parting the roots, and the first sort also plentifully by seed.

By planting slips and cuttings; also by seed. By planting slips, in April, May, and June; also by sowing the seed in the spring season.

By seed sown annually in the spring.

Both by seed sown in the spring season, and the former also by planting slips.

By seed annually, in August, for winter and spring use, or sown also in spring and summer, for succession crops.

An eatable root, raised from seed sown in spring.

By seed in spring; or, if for sallads, at any time of the year.

An eatable root, raised by planting offsets commonly, of the root, also by seeds.

By seed annually in spring.

K N A

NAMES AND SORTS.

Solanum, night-shade, furnishing the potatoe and tomatoe—tuberous-rooted *solanum*, or potatoe—the common round red potatoe—early round red—oblong red—deep red—pale red—rough red—white kidney-shaped—large red-ended kidney—white round—white cluster—prolific American.

Tomatoe, or love-apple; varieties.

Spinacia, spinach—round, thick-leaved, or smooth-seeded—triangular-leaved, or prickly-seeded; the former for spring and summer crops, the latter to stand the winter.

Tanacetum vulgare, common tansy.

Thymus vulgaris, common thyme—the varieties with broad leaves—with narrow leaves—with striped leaves.

Tragopogon porrifolium, salsafy.

Tropaeolum, Indian Cress, or nasturtium—*nasturtium minus*—*nasturtium majus*; their flowers for garnish and sallads, and their seeds to pickle.

Valeriana Locusta, corn-sallad, or lamb's-lettuce.

Vicia Faba, the bean—early Mazagan—early Lisbon—long-pod—Turkey long-pod—toker bean—Sandwich bean—Windsor bean—white-blossomed—red-blossomed—Spanish bean—nonpareil bean—dwarf fan bean, very low.

See the different GENERA.

KNAUTIA, a genus containing plants of the herbaceous, annual, and biennial kind.

It belongs to the class and order *Tetrandria Monogynia*, and ranks in the natural order of *Aggregate*.

The characters are: that the calyx is a common perianthium, containing the floscules disposed in a simple orb, simple, cylindric, oblong, upright: divisions awl-shaped, approximated, of the number of the floscules: perianthium proper, very small, crowning the germ, quite entire, coriaceous, pervious at top: the corolla is universal, equal: proper one-petalled, unequal: tube the length of the calyx: border unequal, four-cleft; the exterior segment larger and ovate: the stamina have four filaments, longer than the tube of the corolla, inserted into the receptacle: anthers oblong, incumbent: the pistillum is an inferior germ: style filiform, length of the stamens: stigma thickish, two-cleft: there is no pericarpium: the seeds solitary, four-sided, crowned with the down, and covered with the proper involucre of the flower:

K N A

MODES OF CULTURE.

By planting pieces of the roots, or the roots whole, in spring; also by sowing seed occasionally to obtain new varieties.

By sowing the seed annually, on a hot-bed, in the spring.

By sowing seed annually, in spring, summer, and autumn, for use most part of the year.

By parting the roots, and planting in spring or autumn.

By sowing seeds in March and April; also by planting slips of the root and branches, and by cuttings; but seed is the only way to raise a quantity of the common sort; and the other methods to continue the varieties, or for a general supply.

An esculent root, by seeds annually in spring.

Raised annually from seeds, sown at different times in spring.

By seed sown in spring and autumn.

By seed sown annually, at different times from October until June, but principally in the early spring months.

the receptacle common, scarcely remarkable, flat, naked.

The species cultivated are: 1. *K. Orientalis*, Oriental Knautia; 2. *K. Propontica*, Levant Knautia.

The first rises with an upright branching stalk four feet high: the branches terminated by single peduncles, each supporting one flower, with the florets of a bright-red colour: the leaves on the middle of the stem are pinnatifid; the rest only serrate: the flowers radiate, with five florets (four). It is annual, and a native of the Levant, flowering from June to September.

The second has the stem biennial, the thickness of a finger, two feet high, villose: the leaves somewhat hairy, rugged; and serrate, except the upper ones, which are quite entire, and a span long: the calyxes oblong, cylindrical, consisting of eight or ten lanceolate leaflets, awl-shaped at the tip: corollas not longer than the calyx, four-cleft; the marginal ones larger, with the outer segment larger, purple: middle corollas often four, smaller, less irregular: anthers pur-

K N A

ple: the filaments and pistils are white. Found in the Levant.

Culture.—These plants may be easily increased by seeds, which, when permitted to scatter in the autumn, produce good plants. They may afterwards be taken up, and planted in the borders of pleasure-grounds, among low shrubs near the walks. The plants in this way live

K N O

through the winter, and flower in June. There is no culture required but to keep the plants clean from weeds. The seeds fall as soon as they are ripe.

They afford variety among other hardy flowering plants of similar growths.

KNEE-HOLLY. See *RUSCUS*.

KNOT-GRASS. See *ILLECEBRUM*.

L A C

LABRADOR TEA. See *LEDUM*.

LABURNUM. See *CYTISUS*.

LABYRINTH, a sort of maze or wilderness plantation, abounding with hedges and walks, distributed into many windings and intricate turnings, leading to one common centre, extremely difficult to be found out, designed by way of amusement.

It is commonly formed with hedges, in double rows, leading in various twistings and turnings, backward and forward, with intervening plantations and gravel-walks alternately between hedge and hedge. The great object is to have the walk contrived in so many mazy intricate windings, as to cause much labour and difficulty to find out the centre, by meeting with frequent stops and disappointments, as the hedges must not be crossed or broken through. In a well-contrived Labyrinth a stranger often entirely loses himself, so as neither to find his way to the centre, or out again the way he came in.

They are now, however, rarely introduced in modern garden designs; and scarce to be seen, except in some old gardens.

The hedges for this use are usually of hornbeam, but may be of beech, elm, or any other sort that can be kept in neat order by clipping. The walks should be five feet wide at least, laid with gravel, and neatly rolled; and the trees and shrubs to form the thicket of wood between the hedges of any of the hardy kinds of the deciduous tribe, interspersed with some evergreens. In the middle, a space should be left open as the centre.

Small Labyrinths are occasionally formed with box edgings, and borders for plants, and alleys for walking in, in imitation of the large ones, and which have a good effect in small garden-grounds.

LAC, or GUM LAC. See *CROTON*.

LACE-BARK. See *DAPHNE*.

L A C

LACHENALIA, a genus containing plants of the bulbous-rooted kinds.

It belongs to the class and order *Hexandria Monogynia*, and ranks in the natural order of *Coronariæ*.

The characters are: that there is no calyx: the corolla has six petals, erected into a tube, oblong, connate at the base, unequal: the three exterior ones shorter, often callous at the tip: the stamina have six awl-shaped, upright filaments, growing to the base of the petals, and of the same length with them: anthers oblong: the pistillum is a superior subovate germ: stigma awl-shaped, length of the stamens: stigma simple: the pericarpium is a subovate capsule, three-winged, three-celled: the seeds several, globose, affixed to the receptacle.

The species cultivated are: 1. *L. orchoides*, Spotted-leaved Lachenalia; 2. *L. pallida*, Pale-flowered Lachenalia; 3. *L. tricolor*, Three-coloured Lachenalia.

The first has a roundish, whitish bulb: the whole of the plant is smooth: the leaves usually two from the bulb, from six inches to a foot in length, one always much narrower than the other, sharpish, thick, spreading at top, flattish, sheathing and channelled at bottom, rough and cartilaginous at the edge, dirty green, marked with lines on the inside, and having dusky spots scattered over them: the scape round, upright, pale green with dusky spots, commonly longer than the leaves: the bractes lanceolate, acuminate, concave at the base, spreading very much, white: the flowers are almost upright; the upper ones in the spike abortive. It is a native of the Cape.

In the second species the bulb is roundish, flattened a little, the size of a hazel nut: the root-leaves two, a foot long and more, acute, channelled, and sheathing at bottom, flat at top, linear-lanceolate, almost equal in length, one

near an inch in width, the other much narrower, deep green on both sides, unspotted, shining, quite entire, and not rough about the edge: the scape round, shining, pale green, unspotted, almost upright, weak: the raceme upright, three inches long, with about twenty flowers, somewhat remote, and inodorous: the bractes sessile, concave, acuminate, whitish: the pedicels one-flowered, round, almost upright, the length of the bractes at least: petals whitish, the three outer wholly green above the middle, the inner marked there only with a green line. It is a native of the Cape.

In the third the leaves two, radical, lanceolate, like those of the common white lily, thin, not fleshy, dusky-spotted on the upper surface: the scape round, like that of the garden hyacinth, scarcely a foot high, dusky-spotted: the flowers alternate: the petals lanceolate, unequal; the three outer fastened to the inner ones, which do not at all cohere at the base: the filaments declining, inserted into the receptacle: the anthers blood-red: stigma white: the stem is almost comose, with abundance of awl-shaped bractes that spring out below the upper rudiments of the flowers.

It varies with yellow, saffron-coloured, blood-red purple at the tip, and greenish yellow corollas; also in the proportion between the inner and outer petals; and in the breadth of the leaves. It is a native of the Cape.

Culture.—These plants may be increased by offsets from the bulbs, and by seeds, when they are produced.

The offsets should be planted out in pots of light fresh earth, when the bulbs are in a state of inactivity of growth, placing them in a warm border to be covered with hand glasses, or, what is better, in a dry stove or green-house.

They bear forcing tolerably, and their flowering is much promoted by being preserved in the warmth of the stove.

They afford variety among collections of potted bulbous-rooted flowering plants.

LACTUCA, a genus containing a plant of the herbaceous annual kind.

It belongs to the class and order *Syngenesia Polygamia Æqualis*, and ranks in the natural order of *Compositæ Semiflosculosæ*.

The characters are: that the calyx is common, imbricated, cylindric: scales very many, sharp, membranaceous on the margin: the corolla compound, imbricated, uniform: corollets hermaphrodite, very many, equal: proper one-petalled, ligulate, truncated, four- or five-toothed: the stamina have five capillary filaments, very short: anther cylindric, tubular: the pistillum is a subovate germ: style filiform, length of the

stamens: stigmas two, reflex: there is no pericarpium: calyx converging, ovate-cylindric: the seeds solitary, ovate, acuminate, even, compressed: down capillary, on a long stipe attenuated below: the receptacle naked.

The species is *L. sativa*, Common Garden Lettuce.

It has the leaves large, milky, frequently wrinkled, usually pale green, but varying much in colour, form, &c. in the different varieties: the stem strong, round, two feet or three quarters of a yard in height, bearing abundance of small yellow flowers. Its native place is unknown; and it is not improbable but that it may be improved by cultivation from one of the wild sorts.

There are several varieties cultivated: the principal of which are, of the Cabbage Lettuce kind, the Hardy Green, White Honey, Great Admirable White, Brown Dutch, Small Early, White Ball, Green Ball; and of the Coss Lettuce kind, the Green Coss, White Coss, Egyptian Coss, Spotted Coss, Black Coss, Brown Cilicia, Green Cilicia, Red Capuchin, Green Capuchin, Large Imperial, the Roman, the Prince: but the three or four first of the different sorts are the most valuable, and it is of much consequence to have the best kinds.

Culture.—This species, and all the varieties, are raised by sowing the seed annually, at different times, as in February and the three following months, for the summer supply of plants; and in August and the following month, for the autumn, winter, and very early spring supplies.

These different sowings should be performed upon beds of fine light dry earth, in an open situation, and exposed to the sun. Some of the late sowings may be made under hand glasses, or in frames or boxes, in order to have the young plants protected from frosts. Each of the varieties or sorts should be sown separately, and distinct from the others, and be slightly raked in.

It is sometimes the practice to sow them among other low growing crops, such as radishes, spinach, onions, &c. to save ground; but this should always be avoided as much as possible, as a very small portion of land is sufficient for raising large supplies of plants.

For the very early spring use, as open Lettuces, the early white cabbage sorts are the most proper; but for the main crops, to remain for full growth, the principal sorts of the Coss and Cabbage kinds must be employed.

When the plants appear, they must be kept perfectly free from weeds, and properly thinned. As they attain a proper growth, as three or four inches in height, some of the different sorts

must be planted out into beds in the open ground, drawing them up carefully, and planting them immediately. This work should be performed by a line and small dibble, in rows, a foot or more distant, with the same space from plant to plant. The quincunx mode is mostly adopted, which affords the most room, and at the same time has the neatest appearance. As soon as the planting is finished, the whole should be well watered; and when the weather is dry, repeated once or twice.

By thus planting out the several sorts at different times, at the distance of three weeks or a month, from the early spring till the latter end of the autumn, due successions of good Lettuces may be provided.

In the summer plantings out, when the weather proves very dry, it is sometimes the practice to plant them in small drills, in order to preserve the moisture more effectually.

After the beds of the different principal sowings have been considerably thinned by the several transplantations that have been made from them, the plants that remain may be set out to proper distances by the hoe, and left to take their full growth.

When the plants of the main spring and summer crops have attained a pretty full growth, especially those of the Coss kinds, it is necessary to tie the leaves of them up with bass pretty close, when the plants are quite dry, in order to blanch the inner parts, and render them perfectly crisp and tender.

Culture in the winter and very early spring crops.—For this purpose some seed of the Hardy Green and White Cabbage sorts, and the Brown Dutch, and White and Green Coss kinds should be sown about the middle of August, and beginning of September, in open situations, when the plants will come up in a week or ten days, and about the end of September; and in October, a parcel of the best plants of each sowing should be planted out in a warm dry situation, five or six inches asunder; and at the latter period some in shallow frames, to be covered with glasses on cold nights, and in bad weather; or under hand-glasses, or in a bed arched over with hoops or rods, to be covered with mats in winter frosts.

Under either of the above shelters the plants should have the free air in mild dry weather, covering them in cold nights with proper covers, especially after this month; also in all very cold, and in very wet weather, day or night, particularly those in the frames and under glasses; and those in hand-glasses may have the glasses almost constantly over them in winter, tilting up one side in mild weather, only setting them

entirely off in fine mild dry days; but in sharp frosty weather keeping those under every kind of shelter quite close; allowing also additional covering of mats or litter, when the frost is very intense. Those in the borders may be defended by some light litter; but the covering should never be suffered to remain longer on any of the crops than the bad weather continues, the free air being admitted every mild day.

In this method Lettuces may be had the greatest part of winter and early in spring, particularly the Cabbage sorts: those planted out first will be fit for use in November and December, and the second plantings come in towards Christmas, and, being sheltered by the glasses, continue coming in for use till succeeded by the other latter autumn sowings; being careful that, as any are gathered out of the frames or glasses, others be removed from the borders to fill up the vacancies, whereby the glasses may be constantly supplied during the winter season.

It is sometimes the practice where Lettuces are intended to be planted in frames late in autumn, for winter use, to have a moderate hot-bed made for their reception, in order that they may be well forwarded in the beginning of winter; and if the heat is continued moderately by aid of linings, allowing plenty of air in mild weather, the plants may be very fine by Christmas or a little after.

Culture in the winter standing spring crops.—In order to have good Lettuces for spring use, some seed should be sown toward the middle and latter end of August, for the plants to stand the winter, some where sown, others transplanted into warm borders, to stand without any other shelter than that of the walls or other fences; and another sowing should be performed about the middle of September, to provide plants for pricking out under frames, to have the shelter of the glasses all winter, as a reserve in case those in the borders are destroyed; where both stand, one may succeed the other as crops.

In the first case a quantity of the best plants, when two or three inches high, should be planted out towards the latter end of October, into a south border, under a wall, &c. and in some other warm dry situation, in rows six inches asunder, and four inches in the rows; or some close under a south wall, or other fence, in a foot-wide space all the way along, pricking them therein four or six inches distant; as they will have a better chance of standing the winter than those situated more distant from the shelter of the wall. In each method the plants are to remain to take their chance all winter: out of the whole many of them will probably escape

the frost; but in very severe weather they may be protected by a light covering of dry long litter, which should be removed again in due time when the frost breaks. In March or April, if they remain too thick, some should be thinned out and planted in another place, in rows twelve or fifteen inches asunder: the crops thus wintered in the open ground, come in for use in April and May, to succeed those sown in autumn, and sheltered occasionally all winter, and will remain good till the spring sown plants are ready for use.

In the latter case, or those sown in September, to be wintered in frames, they should be planted about the latter end of October, or beginning of the following month, in rows, from the back to the front of the frame, three inches distant, closing the earth well about each plant, finishing with a moderate watering all over the plants, and putting on the glasses to promote their more speedy rooting afresh, shoving the lights, however, two or three inches down, to give vent to the moist vapour arising from the mould; but when the plants have taken fresh root, and are set to growing, the full air should be admitted every mild dry day, by taking the glasses entirely off, which must be continued throughout the winter season, in all dry mild weather, but putting them on every night in cold or very wet weather; also in the day-time when great rains prevail; and in frosty weather keeping the glasses always on, except in the middle of sunny days, and when the frost is but slight; using also other coverings of mats or long litter over the glasses, and around the sides of the frame, when the frosts are very severe; during the winter keeping all decayed leaves clean picked off; and as the spring and warm weather advance, letting them have the benefit of warm showers. In this way they may be effectually preserved, if those in the open ground should be destroyed by the frost or excessive moisture. About March some of them should be transplanted into the open ground, in rows, a foot asunder, watering them moderately till fresh rooted; leaving a crop remaining in the frames or winter-bed, a foot apart, to stand to cabbage; which will arrive to perfection a considerable time before the transplanted ones, and those that have been fully exposed all winter, are ready. Where frames cannot be spared, a quantity of the plants may be pricked out under hand- or bell-glasses in autumn, to stand the winter, either by themselves for a full crop, or some under the hand- or bell-glasses, that are placed over early cauliflowers, as practised by the London gardeners, planting them round just within the glasses, and managing them as di-

rected for those in the frames; or for want either of a sufficiency of frames or hand-glasses, a quantity may be planted out in October, in four-feet wide beds, in a warm situation, arched over with hoops or rods, to cover with mats and litter in bad weather. In this way they have a better chance of surviving the winter than those fully exposed; and in spring transplanting a quantity, by way of thinning, into other beds, as directed above.

Saving seed.—For this purpose some of the best cabbaged early plants of all the sorts should be chosen, as those of the latter crops rarely run soon enough to ripen seeds perfectly before they are attacked by the autumnal rains and cold, which greatly retard the ripening of the seed.

It is likewise of importance to have the different varieties intended for seed at some distance from each other, as when too near together, the farina of the different sorts may mix and fecundate one another, and thereby degenerate plants be produced.

The seed usually ripens in August and September, but that of different plants rarely equally together; so that, as it arrives to perfection, the respective stems, &c. of ripe seed should be pulled up or cut off in dry days, and spread upon a cloth, or tied in small bunches, and hung up across lines in a dry airy place for a week or two, for the seeds to become dry and harden; then beaten or rubbed out, and cleaned from the down and other rubbish, and exposed upon cloths a few days to dry for keeping; being afterwards put up in bags for use, and hung in a dry room.

These plants may in general be considered as annuals and biennials; as those sown in spring and summer attain perfection, run up to seed, and perish the same year; while the autumn sowings stand all winter until the spring following, when they attain perfection, shoot up to seed, and perish root and branch. All the sorts are sufficiently hardy to grow in any good dry common soil, in a free situation open to the sun and air.

The use of these plants is principally in sallads, when arrived at full growth and cabbaged, that the inner leaves become blanched, crisp, and sweet; and sometimes also the young open plants of the Cabbage Lettuce sorts are used in winter and spring, till the other general crops arrive at perfection. Young open Lettuces are also often used as small sallad herbs, sowing them thick in rows, like cresses, &c. and gathering them in the same manner; but this mode is more particularly practised in winter and early spring. They, however, in general, do not eat any way so crisp, sweet, and palatable as when fully cab-

bagged. The fully cabbaged Lettuces are also excellent for stewing and for soups, as well as many other purposes.

LADANUM. See CISTUS.

LADIES' BOWER. See CLEMATIS.

LADIES' MANTLE. See ALCHEMILLA.

LADIES' SLIPPER. See CYPRIPEDIUM.

LAGERSTROEMIA, a genus containing a plant of the exotic tree kind, for the greenhouse.

It belongs to the class and order *Icosandria Monogynia*, and ranks in the natural order of *Salicaceæ*.

The characters are: that the calyx is a one-leaved, six-cleft, bell-shaped perianthium, rather acute, smooth, permanent: the corolla has six ovate, obtuse petals, crisped, undulated, contorted: claws filiform, longer than the calyx, inserted into the receptacle: the stamina have very many filiform filaments, longer than the calyx, inserted into the calyx below the germ: the six exterior ones are twice the thickness of the rest, and are longer than the petals: anthers oval, incumbent: the pistillum is a subglobose germ: style filiform, length of the longer stamens: stigma simple: the pericarpium is a subglobose capsule, crowned with the style on its bluntish top, six-furrowed, six-celled, six-valved, the dissepiments coalescing with the sutures: the seed several, ovate, awl-shaped at the base, compressed, adhering to a central hexagonal pillar.

The species cultivated is *L. Indica*.

It has the trunk about a fathom high, or somewhat more, smooth all over: the branches alternate, somewhat angular, flexuose, rigid, spreading: the branchlets four-cornered: the leaves alternate, subsessile, on the twigs ovate, on the branches oblong, obtuse, entire, nerved, stiffish, from half an inch to an inch in length: the flowers in a decomposed, trichotomous, naked, spreading panicle at the ends of the twigs. It is a native of the East Indies, &c. flowering from August to October.

Culture.—This plant is capable of being increased either by layers or cuttings of the young branches.

The layers should be made from the young shoots of the preceding summer, and be laid down in the autumn. When they are well rooted in the succeeding autumn, they should be taken off and planted out in separate pots.

The slips or cuttings should be made from shoots of the same year's growth, and be planted out early in the summer, in pots of light earth, being plunged in a bark hot-bed, and covered with small bell hand-glasses, due shade and water being given. When well rooted in

the spring following, they may be taken up and planted in separate pots, filled with light mould, being afterwards managed as other green-house plants.

They afford variety in collections of potted plants.

LAGOECIA, a genus containing a plant of the herbaceous kind.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Umbellatæ* or *Umbelliferae*.

The characters are: that the calyx is an universal involucre, eight-leaved: leaflets feather-toothed, ciliated, reflex, containing the umbelule: involucre proper four-leaved: leaflets hair-feathered, involving a single footstalk shorter than the leaflet itself: perianthium proper five-leaved, hair many-cleft, superior: the corolla has five two-horned petals, shorter than the calyx: the stamina have five capillary filaments, length of the corolla: anthers roundish: the pistillum is a roundish germ, below the receptacle of the perianthium: style length of stamens: stigmas two, the one truncated: there is no pericarpium: the seeds solitary, ovate-oblong, crowned by the perianthium.

The species is *L. cuminoides*, Wild or Bastard Cumin.

It is an annual plant, about a foot high: the leaves resemble those of Honeywort: the flowers are collected into spherical heads at the extremity of the stalks, and are of a greenish yellow colour: the fruit is small, pedicelled, ovate-acuminate, crowned with a ciliate calyx, villose, one seed only ripening, the other abortive, and fixed laterally to the apex of the other, like a withered scalelet: the fertile seed is of a dusky black colour, sprinkled all over with hoary villose hairs, convex on one side, with five capillary raised whitish streaks, flattish on the other, with three very slender streaks, marking out the place of the abortive seed, which is constantly and easily found when the fruit is well softened in water. It is a native of the Levant, flowering in June and July.

Culture.—These plants may be increased by sowing the seeds in autumn, on a warm border, soon after they are ripe, or where they are to remain; or when permitted to scatter, they come up and form good plants. They afterwards require only to be kept clean from weeds, and in the former cases planted out, when of sufficient growth, where they are to grow.

They afford ornament and variety in the borders and other parts of shrubberies.

LAMB'S LETTUCE. See VALER NA.

LANTANA, a genus containing plants of the shrubby, exotic, green-house, and stove kinds.

It belongs to the class and order *Didynamia Angiospermia*, and ranks in the natural order of *Personatae*.

The characters are: that the calyx is a one-leaved perianthium, very short, converging, obscurely four-toothed, tubular: the corolla one-petalled, nearly equal: tube cylindric, slender, longer than the calyx, rather oblique: border flat, unequally four-cleft, obtuse: the stamina have four filaments, very small, placed in the midst of the tube of the corolla, very slender, of which two are a little higher: anthers roundish: the pistillum is a roundish germ: style filiform, short: stigma refracted, sharp downwards like a hook, and as it were obliquely growing to the tip of the style: the pericarpium is a roundish, one-celled drupe: the seed a round-pyramidal, three-celled nut: the lowest cell sterile: the kernels solitary, oblong.

The species cultivated are: 1. *L. mista*, Various-flowered Lantana; 2. *L. Camara*, Various-coloured Lantana; 3. *L. involucrata*, Round-leaved Lantana; 4. *L. melissifolia*, Baum-leaved Lantana; 5. *L. aculeata*, Prickly Lantana; 6. *L. aurea*, Golden-flowered Lantana.

The first is about five feet in height: the trunk round or roundish, with an ash-coloured bark: the branches at top, several, short, ash-coloured, and from these several others, a long span or a foot in length, quadrangular, green, hairy: the leaves above bright green and somewhat shining, beneath paler, deeply notched, much wrinkled, and very rugged: whilst the flower is yet closed, the lower part of the border appears of a pale red; when it opens, the tube and upper part of the border are saffron-coloured, but become reddish, and finally dark red: this change of colour begins from the circumference and finishes in the centre: hence the flowers in an umbel not being all opened at once, the middle appears of a saffron yellow, and the circumference of a red colour, whence the name. It is a native of America.

The second species has a shrubby stem, a fathom in height, angular, somewhat rugged: the branches subdivided, almost upright, rugged, quadrangular: the branchlets quadrangular, grooved, strict, hirsute, dark green: the leaves on long petioles, decussated, spreading, ovate, acuminate, serrate, nerved, hirsute: the flowers terminating: the peduncles shorter than the leaves, solitary, angular, grooved, hirsute: the bractes broad-lanceolate, concave, entire, pubescent. It is a native of the West Indies, flowering from April to September.

The third has a round woody stem, branched, scarcely hairy: the branches opposite: the leaves petioled, scarcely crenate, membranaceous,

ecous, rigid, less wrinkled than in the others above, nerved beneath, tomentose: the leaves seldom if ever in threes: the peduncles short: the spikes rounded: the bractes large, sessile, cordate-ovate, with six or more nerves running in right lines from the centre, all a little excavated their whole length, and tomentose: the flowers whitish, with pale flesh-coloured margins. It is a native of the West Indies, flowering from May to July.

The fourth species is lower than most of the others, being seldom more than two feet in height: the stem round, ash-coloured, not hairy: the younger branches have bundles of hairs spreading out at top: the leaves opposite, but sometimes in threes, petioled, cordate-acuminate, more deeply crenate than in the other species, wrinkled, rugged and green on the upper surface; paler and tomentose-hairy underneath: the flowers axillary, with three peduncles, where there are three leaves: the bractes oblong, entire, tomentose-hairy, deciduous, differing in size: the colour of the corolla constant, and always yellow. It is a native of South America.

The fifth has the stem in its native situation ten feet high, an inch and a half thick, square from top to bottom, armed with long, strong, reflex prickles, or rather thorns, for they cannot be torn off without injuring the wood; but in the stove only five or six feet in height: the leaves ovate-oblong or cordate-oblong, wrinkled, rugged, crenate: the peduncles long, with fewer and shorter prickles: the colour of the tube of the corolla pale red: border lemon-coloured, changing into an orange and sometimes a deeper colour: the peduncles are terminated by roundish heads of flowers; those on the outside are first of a bright red or scarlet, and change to a deep purple; those in the centre are of a bright yellow, and change to an orange colour. It is a native of the West Indies, flowering from April to November.

The sixth species has the stem seven feet high, at first obscurely quadrangular, but afterwards round, striated, very thinly beset with prickles, and not hairy: the leaves ovate-oblong or almost elliptic, bluntly notched about the edge, very short stiff hairs at the upper surface, the lower rugged with a harsh down, dark green and shining as if they were varnished: the peduncles short: the bractes deciduous, short: the colour of the flower yellow, becoming golden and then saffron-coloured. It is a native of the Bahama Islands.

Culture.—These plants are capable of being raised by seeds and cuttings of the young branches.

The seeds should be sown in pots of light mould in the early spring, plunging them in a bark hot-bed. When the plants have attained some inches growth, they should be removed into separate pots of a small size, and be replunged in the bark-bed, due shade and air being given. The plants should afterwards, when they have acquired strength, be removed into an airy glass-case, or dry stove, where they may have a large share of air in warm weather, but be protected from the cold. This is necessary for the young plants, which should not the first year be exposed to the open air, but afterwards they may be placed abroad in the warmest part of summer, and in winter be placed upon stands in the dry stove, where they will continue long in flower, and many of the sorts ripen their seeds. In winter they should be sparingly watered, as much moisture rots their roots.

The cuttings should be planted in pots in the spring and summer months, as in July, and be plunged in a moderate hot-bed, due shade being given.

They soon take root, and should afterwards be removed into separate pots filled with light earth, and managed in the same manner as those raised from seed.

They afford ornament and variety among collections of stove and green-house plants.

LARCH TREE. See PINUS.

LARKSPUR. See DELPHINIUM.

LATHYRUS, a genus containing plants of the herbaceous climbing flowery kinds.

It belongs to the class and order *Diadelphia Decandria*, and ranks in the natural order of *Papilionaceæ* or *Leguminosæ*.

The characters are: that the calyx is a one-leaved perianthium, half five-cleft, bell-shaped: divisions lanceolate, sharp: the two upper ones shorter; the lowest longer: the corolla papilionaceous: standard obcordate, very large, reflex on the sides and tip: wings oblong, lunulate, short, obtuse: keel half-orbicular, size of the wings, and wider than the wings, gaping inwards in the middle: the stamina have diadelphous filaments, (single and nine-cleft) rising upwards: anthers roundish: the pistillum is a compressed germ, oblong, linear: style erected upwards, flat, wider above, with sharp tip: stigma, from the middle of the style to the tip villose in front: the pericarpium is a legume, very long, cylindric or compressed, acuminate, one-celled, bivalve: the seeds several, cylindric, globose, or but little cornered.

The species cultivated are: 1. *L. odoratus*, Sweet Lathyrus, or Pea; 2. *L. Tingitamus*, Tangier Lathyrus, or Pea; 3. *L. latifolius*, Broad-leaved Lathyrus, or Everlasting Pea.

Several other species may be cultivated where variety is wanted.

The first is an annual plant, which rises from three to four feet high by means of its long claspers or tendrils: the flower-stalks come out at the joints, are about six inches long, and sustain two large flowers, which have a strong odour, and are succeeded by oblong hairy pods, having four or five roundish seeds in each. It is a native of Sicily.

There are several varieties; as the purple-flowered, the white-flowered, the variegated or painted lady, sweet-scented, and the scarlet.

The second species has the stem four or five feet high: the leaflets veined: the peduncles short, sustaining two large flowers with purple standards, the wings and keel bright red: the legumes long, jointed, containing several seeds.

Martyn observes, the whole plant is very smooth: the stem branched, running out on each side into a slender sharp wing: the petioles angular, ending in bifid, trifid or simple tendrils: the stipules lanceolate, acuminate, produced downwards into an earlet, similar but much smaller: the peduncles sometimes one-flowered. It is a native of Barbary, flowering in June and July; and although it has not the agreeable scent, or variety of colours, or continuance in blow of the Sweet Pea, it is usually sown in gardens with other annual seeds.

The third has a perennial root: the stalks several, thick, climbing by means of tendrils to the height of six or eight feet, or even higher in woods: these die to the ground in autumn, and new ones rise in the spring from the same root: the leaves stiff, marked with three or five strong ribs, rolled in at the edge, blunt at the end, but terminating in a little point or bristle; they are always in pairs, and on a winged petiole; at the base of this are large stipules, shaped somewhat like the head of a halbert: the tendrils multifid or branched: the peduncles eight or nine inches long. Each flower has an awl-shaped bracte at the base of the pedicel: the corolla pale purplish rose-colour: the legumes an inch and half long, and half an inch in breadth. It is a native of many parts of Europe, flowering at the end of June and beginning of July.

It is a showy plant for shrubberies, wilderness quarters, arbours, and trellis-work; but too large and rampant for borders of the common flower-garden.

There are many varieties; as the red-flowered, the purple-flowered, the scarlet-flowered, and the large-flowered.

Culture.—These plants may be readily raised, by sowing the seeds of the different sorts in the

autumn or spring seasons at different times, in patches of six or eight together, in the places where they are to grow. Where the soil is light and dry, the autumn is the best season, as the plants appear more early, but in other cases the spring should be preferred. The plants afterwards only require to be kept clean from weeds, and be properly supported by branchy sticks.

The last sort may likewise be increased by transplanting the roots in the autumn; but the plants in this way are seldom so good as by seeds.

The two first sorts must be sown annually, but the last will remain many years.

It is the practice with the gardeners who raise the first sorts for the London markets, to sow them in the autumn in pots, and secure them from severe weather, by placing them in hot-bed frames; by which means they can bring them much more early to market. They may be continued in flower the whole summer by repeated sowings in the spring. When sown in pots they should be watered frequently.

They are all highly ornamental in the borders, clumps, and other parts of pleasure-grounds, when properly intermixed in their species and different varieties.

LAVANDULA, a genus comprising plants of the shrubby evergreen kind.

It belongs to the class and order *Didynamia Gymnospermia*, and ranks in the natural order of *Verticillatæ*.

The characters are: that the calyx is a one-leaved perianthium, ovate: mouth obscurely toothed, short, permanent, supported by a bracte: the corolla one-petalled, ringent, resupine: tube cylindric, longer than the calyx: border spreading: one lip looking upwards, larger, bifid, spreading: the other lip looking downwards, trifid: divisions all roundish, nearly equal: the stamina have four short filaments, within the tube of the corolla, deflected, of which two are shorter: anthers small: the pistillum is a four-parted germ: style filiform, length of the tube: stigma two-lobed; obtuse, converging: there is no pericarpium: calyx converging with the mouth and guarding the seed: the seeds four, obovate.

The species cultivated are: 1. *L. Spica*, Common Lavender; 2. *L. Stæchas*, French Lavender; 3. *L. dentata*, Tooth-leaved Lavender; 4. *L. multifida*, Canary Lavender.

The first has a perennial, thick, woody root: the stem shrubby, much branched, frequently five or six feet high, four-cornered, acute-angled, tomentose: the leaves numerous, blunt, hoary, the upper ones sessile, the lower petioled: the flowers are produced in terminating spikes from

the young shoots, on long peduncles; the spikes are composed of interrupted whorls in which the flowers are from six to ten, the lower whorls more remote: each flower upright, on a short pedicel: the bractes broad-ovate, awned, acuminate, veined: the common colour of the corolla is blue, but it varies with white flowers: the whole plant is covered with a down composed of forked hairs. It is a native of the South of Europe, flowering here from July to September.

There are varieties with narrow leaves with blue flowers, and with white flowers with broad leaves, and Dwarf Lavender.

This species is the Common Lavender; but the narrow-leaved variety with blue flowers is the sort cultivated for its flowers, for medicinal purposes.

The broad-leaved sort has much shorter and broader leaves, and the branches are shorter, more compact, and fuller of leaves: it continues several years without producing flowers; and when it does, the leaves on the flowering-stalks approach nearer to those of the Common Lavender, but are still broader: the stalks grow taller, the spikes are looser and larger, the flowers smaller, and appear a little later in the season.

The second species has a low, thick, shrubby stalk, about two feet high, sending out woody branches the whole length: the leaves about an inch long, hoary and pointed, of a strong aromatic scent, opposite at each joint, with smaller leaves of the same shape coming out at the same places: the branches are terminated with scaly spikes of purple flowers, four-cornered, and an inch in length; and at the top is a coma or small tuft of purple leaves. When it begins to flower, there are only four flowers in a whorl, but these are afterwards increased by the lateral gems, till it becomes gradually round. The whole plant has a very strong, aromatic, agreeable odour. It is a native of the South of Europe, flowering from May to July.

There are varieties with white flowers; and with purple flowers.

The third species has a woody stalk two or three feet high, with four-cornered branches on every side the whole length: the leaves are opposite about an inch long, and an eighth of an inch broad, indented regularly on both sides almost to the midrib, of a grayish colour, a pleasant aromatic odour, and a biting warm taste: the flowers are produced in scaly spikes at the ends of the branches upon long naked peduncles: the spikes are four-cornered, hairy, and about an inch long, terminated by a few purplish leaves. It is a native of Spain, flowering from June to September.

The fourth is an annual (or rather a biennial)

plant, with an upright branching woolly stalk two feet high: the leaves hoary, opposite, cut into many divisions to the midrib: these segments are again divided on their borders towards the top into three blunt ones, so that they end in many points: the peduncle is continued from the end of the branch, is naked, and about six inches long, quadrangular, and terminated by a close spike of flowers about one inch long: the rows of flowers are twisted spirally. There are commonly two small spikes below this, and about an inch from it: the corolla varies from blue to white. It is a native of Spain.

There is a variety which rises with an upright, branching, square stalk, four feet high: the leaves longer, and cut into narrower segments than the Spanish plant: they are of a lighter green, and almost smooth: the naked flower-stalk is also much longer, and terminated with a cluster of spikes of blue flowers: at two or three inches below these are two small spikes, one on each side: the flowers are smaller than those of the first sort. It is a native of the Canary Islands.

Culture.—All the sorts are readily increased, by planting slips or cuttings of their young shoots in the spring.

In the first two sorts, a quantity of slips or cuttings should be taken off in the early spring, as March or April, from three or four to six inches long, stripping off the underleaves, then planting them in a shady border four inches asunder, giving a good watering, and repeating it occasionally in dry weather. When the plants are well rooted in summer, they should be transplanted into the place where they are to grow, early in autumn, as September or October, with balls of earth about their roots.

When the first sort is intended to produce flowers for economical purposes, it should be planted in rows, two or three feet asunder, and about the same distance in the rows, or in a single row one or two feet asunder, along the edge or divisions of garden-grounds, in a sort of edging or dwarf hedge; in either of which modes the plants grow freely, continuing in root, stem and branches several years, and produce abundance of spikes of flowers annually for gathering in the latter end of summer: the culture afterwards is principally to cut down any remaining decayed flower-stalks in autumn, pruning or cutting away any disorderly out-growing branches at top and sides, and digging the ground occasionally in spring or autumn along the rows of plants.

The second sort may also often be raised from seeds, which should be sown in a bed of light earth in the early spring, and raked in evenly

with a light hand. The plants rise in about a month, when, if there be dry weather, water should be given; and after they are three inches high, they should be pricked out in beds, half a foot apart, watering them as they require, until fresh rooted. They should stand here till the following spring, and then be transplanted out, and planted where they are to remain.

The two first sorts are useful for their fine spikes of flowers, as well as ornaments in assemblage with other shrubby plants, in the borders and clumps of pleasure-grounds; and the two last sorts in green-house collections with other potted plants.

Those designed for shrubberies or other similar places, being previously raised to some tolerable bushy growth, and a foot high or more, should be planted either in the early autumn, or in the spring, disposing them singly at proper distances in the fronts.

The third and fourth sorts may be increased by slips and cuttings, planted in pots in the early spring months, and placed under frames, to shelter and shade from the mid-day sun, till they are rooted; and when a little growth, transplanted into separate pots, and managed as other green-house exotic plants.

LAVATERA, a genus containing about ten species of the herbaceous shrubby perennial kind.

It belongs to the class and order *Monadelphæa Polyandria*, and ranks in the natural order of *Malvaceæ*.

The characters are: that the calyx is a double perianthium: exterior one-leaved, trifid, obtuse, short, permanent: interior one-leaved, trifid, more acute, more erect, permanent: corolla has five obcordate flat petals, none of which are affixed below to the tube of the corolla: the stamina have numerous anthers, which coalesce below into a tube, the exterior of which is bristly, length of the tube about the length of the anther: the pistillum is an orbicular capsule, as there are stigmas, and a whorl round the capsule, the seeds falling off: the seeds solitary.

The species cultivated are *Malva*, *Cretan Lavatera*; 2. *L. trimesitis*, *Cretan Annual Lavatera*; 3. *L. Thuringiaca*, *Great-flowered Lavatera*; 4. *L. arborea*, *Tree Lavatera*, or *Mallow*; 5. *L. Olbia*, *Downy-leaved Lavatera*; 6. *L. triloba*, *Three-lobed Lavatera*; 7. *L. Lusitanica*, *Portuguese Lavatera*.

The first has an annual fibrous root of thick fibres, a foot in length, with innumerable other capillary fibres: the stem round, rugged, five

Lavatera Trimestris
1 Annual Lavatera

Lathyrus Sativus
2 Blue flowered Lathyrus

feet high, branched: the leaves on long petioles, very soft, tomentose, toothed, seven-angled, the angles of the upper ones sharper: the stipules lanceolate, ciliate, bowing at bottom and then erect: the flowers axillary, about four together, on upright peduncles: the outer calyx cup-shaped, with ovate segments: inner a little longer, five-cornered above, with lanceolate segments: the corolla twice the length of the calyx, pale blue, with oblong, emarginate petals: the germ orbicular-flattened, ten-grooved: the stigmas ten: the fruit smooth, within the calyx: the capsules ten, round a column terminated by a hemisphere with a very small point at top, disappearing when the fruit is ripe, and leaving a hole in the middle of the capsules, which then turn black. It is a native of the island of Candia or Crete, flowering in July.

It varies with red flowers, with white flowers, and with purple flowers.

The second has also an annual root, white, with spreading beards: the stem round, two feet high, branched, the lower branches almost horizontal: the leaves crenate-toothed, smooth, on long petioles, gradually narrowed towards the tip: stipules ovate-lanceolate, ciliate, bowed at bottom and then straight: the flowers solitary, axillary, on peduncles shorter than the petiole: outer calyx semi-trifid, with keeled segments; inner larger, with lanceolate segments, curled at the edge: the corolla large, spreading, bell-shaped, pale flesh colour, with whitish lines: petals broader above, crenate, frequently rolled up, the edges of the claws deep purple: the germ very smooth: the style multilid: the stigmas pale-flesh-coloured, longer than the tube, thirteen to eighteen: the fruit hemispherical, convex beneath, covered at top with a circular, concave, smooth lid or peltate umbrella: there are about twenty capsules in a whorl; they are brown, closed all round and not opening, with a longitudinal raised line along the back, elegantly marked on the sides with flexuose streaks drawn from the circumference to the centre: the seeds are ferruginous. It is a native of the South of Europe, &c. flowering from July to September.

There are several varieties.

The third has the stem five or six feet high, woolly, branched: the lower leaves heart-shaped, crenate, roundish-lobed: upper hastate, on short petioles: the stipules lanceolate: the flowers axillary, solitary, peduncled; peduncles longer than the leaf: the calyxes subtomentose: the segments of the outer heart-shaped, with a very sharp point; of the inner oblong acute: the corolla large, spreading, pale violet or purplish, shaped like those of the Marsh-mallow, but larger: petals emarginate: the capsules

about twenty (fourteen) in a wing of a papery substance, somewhat rugged, about a columnar receptacle, which has many wings from the permanent sides of the capsules, like the cogs of a mill wheel, ending in a conical awl-shaped point: the seeds flattened a little, smooth, subcinereous or brown. It is a native of Sweden, flowering from July to September.

The fourth species rises with a strong thick stalk the height of eight or ten feet (in gardens), dividing into many branches at the top: in its wild state, when largest, from four to six feet high, and as much as four inches in diameter: the leaves are alternate, numerous, cordate, roundish-seven-angled (some five- and others three-angled), the angles blunt, soft as velvet, shorter than the petioles: the stipules short, smooth, acuminate at the tip, broad at the base: the flowers mostly in pairs, sometimes three together, on upright peduncles an inch and a half in length: the outer calyx ovate at the base, divided half way into three broad blunt segments; inner only half the size, divided half way into five sharp segments: the corolla purplish red, with dark blotches at the base, spreading bell-shaped (like that of the common Mallow), an inch or more in diameter: the petals broader at top, narrow at the base, so that the calyx appears between the claws: the cylinder of filaments purple, woolly at the base: the germ very smooth: the style usually eight-cleft at top: the stigmas revolute, reddish: the ring or whorl of fruits is seven- or eight-capuled: the common receptacle awl-shaped, with a conoid globe at top, and small crescent-shaped lamellæ at the base and the interstices of the capsules: the capsules are reniform-rounded, sharply three-cornered, membranaceous, wrinkled, closed on all sides, pale bay-coloured, not opening: the seeds kidney-shaped, and ash-coloured. It is a native of Italy, &c. flowering from June or July to September or October.

The fifth has a round branched stem, five feet high, villose at top, reddish: the leaves soft, whitish, tomentose, unequally serrate; the lower subcordate-hastate, five-angled; the upper ovate, three-cusped, the middle lobe narrowed, acute, oblong: the stipules ovate-lanceolate, villose: the flowers on short peduncles, axillary, solitary, very seldom two together; terminating ones in a spike: the outer calyx ovate, with roundish-acute segments; inner larger, with lanceolate-acute segments: the corolla large, spreading very much, reddish-purple: the petals with narrowed claws, covered with white hairs, inserted into a flesh-coloured tube: the stamens purple: the germ roundish-compressed, with twenty grooves: the style divided into about twenty

parts: the stigmas long, recurved: the capsules about twenty, black, smooth, fixed in a ring about a thick striated cone: when the seeds are ripe, that part which is next to the axis appears naked, on account of the pellicle which forms the internal part of the capsule adhering to the axis. According to Linnaeus, the leaves of the first year are very large, and those of the following much smaller, which is a circumstance common to this with other plants of the same natural order. It is a native of the South of France, flowering from June to October.

The sixth species has a round branched stem, from three to four feet in height: the leaves are alternate, petioled, shorter than the petioles, roundish, but with the border so rolled back as to appear triangular: the stipules cordate, broad, acuminate, serrate: the flowers axillary: three peduncles, mostly one-flowered, in each axil, upright, shorter than the petiole: the segments of the outer calyx broad-cordate, acuminate: the inner calyx twice as large, five-cornered, acuminate, with the corners prominent: corolla large, spreading, pale purple, with the claws white, hairy: the capsules about fifteen, in a ring about a column ending in a point. According to Linnaeus, the whole plant is tomentose, being covered with very small glutinous hairs, with other larger ones stellate at top mixed among them. It is a native of France and Spain, flowering from June to September.

The seventh is a native of Portugal, flowering in August and September.

Culture.—The first two, or annual sorts, are readily increased, by sowing the seeds in a light soil in the places where the plants are to remain, or in pots, in the spring season, as about the latter end of March, in patches of four or five in each, giving them water occasionally when the weather is dry. When the plants have attained a little growth, they should be thinned out to one or two of the strongest plants. When any are to be removed to other places, it should be done at this period, and with a little earth about the roots, due water and shade being given; but they seldom succeed well by transplanting.

All the other shrubby perennial sorts may likewise be increased by sowing the seeds, and managing the plants in the same manner.

Most of these sorts will not last more than two years in this climate, unless the soil be dry, when they continue three or four.

They in general require a warm dry situation, or to have their roots covered by old tan, or the protection of the green-house during the severity of the winter season.

They are all highly ornamental in different

parts of pleasure-grounds. The annual sorts have great beauty, in their flowers being large, numerous, and conspicuous, and are proper where large showy-flowering plants are required. The perennial kinds are also suitable for large borders and shrubby compartments, having large, straight, upright, durable stems, terminated by branchy bushy heads, and very large soft foliage, that form a fine variety in assemblage with other plants, though their flowers are often hidden by their large leaves.

LAUREL. See LAURUS and PRUNUS.

LAUREL SPURGE. See DAPHNE.

LAUREOLA. See CESTRUM and DAPHNE.

LAURESTINE. See VIBURNUM TINUS.

LAUROCERASUS. See PRUNUS.

LAURUS, a genus containing plants of the evergreen and deciduous tree kinds for the borders, green-house, and stove.

It belongs to the class and order *Enneandria Monogynia*, and ranks in the natural order of *Holoraceae*.

The characters are: that there is no calyx (unless the corolla be so called): the corolla has six ovate acuminate petals, concave, erect: the alternate ones exterior: nectary consisting of three acuminated coloured tubercles, ending in two bristles, standing round the germ: the stamina have nine filaments, shorter than the corolla, compressed, obtuse, three in each rank: anthers growing on each side to the margin of the filament on the upper part: glandules two, globose, with a very short footstalk, affixed to each filament of the inner rank near the base: the pistillum is a subovate germ: the style simple, equal, length of the stamens: stigma obtuse, oblique: the pericarpium is a drupe (or berry), oval, acuminate, one-celled, comprehended by the corolla: the seed is an ovate-acuminate nut: the kernel of the same form.

The species cultivated are: 1. *L. nobilis*, Common Sweet Bay; 2. *L. æstivalis*, Willow-leaved Bay; 3. *L. Benzoin*, Common Benjamin-tree; 4. *L. Sassafras*, Sassafras-tree; 5. *L. Indica*, Royal Bay, or Indian Laurel; 6. *L. Borbonia*, Broad-leaved Carolina Bay, or Red Bay; 7. *L. Camphora*, Camphor, or Gamphire-tree; 8. *L. Cinnamomum*, Cinnamon-tree; 9. *L. Cassia*, Cassia, or Wild Cinnamon-tree; 10. *L. Persea*, Alligator Pear.

The first in this climate appears as a shrub, but in the southern parts of Europe it becomes a tree of twenty or thirty feet in height; much subject, however, in general, to put out suckers: the leaves are evergreen, of a firm texture, the largest from an inch and a half to two inches in

breadth in the broad-leaved variety, and from three to four inches in length, entire, on short petioles, having an agreeable smell, and an aromatic, subacid, bitterish taste: the flowers are dioecious, or male and female on different trees, in racemes shorter than the leaves, of an herbaceous colour: the corollas four-petalled in the male flowers, with from eight to twelve stamens: the berry superior, ovate, fleshy, dark purple almost black: the receptacle none, except a small tubercle at the bottom, whence a vascular band rises on each side the whole length of the seed; which is large, ovate, slightly mucronate above. It is a native of the southern parts of Europe, and of Asia.

There are several varieties; as the broad-leaved, which is almost too tender for the open air in this climate, with leaves much broader and smoother than those of the common sort;—the common, which is seldom hurt in this climate, except in very severe winters, of which there are two subvarieties, one with plain leaves, the other with leaves waved on the edges;—the narrow-leaved, with very long narrow leaves, not so thick as those of the preceding two sorts, and of a light green, the branches covered with a purplish bark, and the male flowers come out in small clusters from the axils of the leaves, sitting close to the branches; of which there are subvarieties in the nurseries with variegated leaves.

What is now called Bay was formerly called Laurel, which has introduced some confusion.

The second species rises with a shrubby branching stalk eight or ten feet high, covered with a purple bark: the leaves are opposite, near two inches long and one inch broad, smooth on their upper side, but veined on their under, where they are rough: the berries red, nearly the size and shape of the common Bay-berry. It is a native of North America.

The third rises to the height of ten or twelve feet, dividing into many branches: the leaves are near three inches long, and an inch and a half broad, smooth on their upper surface, but with many transverse veins on their under side: the flowers of a white herbaceous colour, with six stamina in each: the involucre is sessile, four-leaved, much resembling that of *Cornus*, including five petioled florets, the length of the involucre: proper calyx (or corolla) six-parted, yellow, with linear segments: the stamens eight or nine, the length of the calyx, appendicled on the sides: the germ ovate, within the calyx: the style simple. It is a native of Virginia.

Martyn observes that it has been confounded with the true Benzoin tree. See *STRYAX BENZOIN*.

The fourth species is commonly a shrub, seldom rising more than eight or ten feet high (it sometimes, however, grows into a large tree): the leaves are of different shapes and sizes; some oval and entire, about four inches long and three broad; others are deeply divided into three lobes; these are six inches long, and as much in breadth from the extremity of the two outside lobes; they are placed alternately on pretty long footstalks, and are of a lucid green; they fall off early in the autumn; and in the spring, soon after the leaves begin to come out, the flowers appear just below them, on slender peduncles, each sustaining three or four small, yellow (greenish white) flowers, which have five oval concave petals, and eight stamina in the male flowers, which are upon different plants from the hermaphrodite flowers: these are succeeded by an oval berry, which, when ripe, is blue. It is a native of America. Its wood is of a light and spongy texture, having a fragrant smell, and a sweetish aromatic taste.

The fifth is a large tree with ascending branches: the branches, and particularly the shoots, are tubercled with scars from the fallen leaves; they are alternate, curved inwards, wrinkled and smooth: the leaves scattered, acuminate with a bluntish point, quite entire, smooth, veined, reflex, four inches long: the petioles semi-cylindric, grooved, smooth, reflex: the flowers terminating, below racemed, above panicled: the panicle trifid: ovate, red nectareous scales at the base of the filaments, which vary in number from seven to nine; six outer, and one, two, or three inner: they are unequal, flat, and nearly equal to the calyx: the anthers compressed, four-celled: the germ roundish: the style very short: the berry globular, small, and brown. It is a native of Madeira.

The sixth species rises with a straight large trunk to a considerable height near the sea; but in the inland parts of the country it is of hamble stature: the leaves are much longer than those of the Common Bay, and are a little woolly on their under side; their edges are a little reflexed; the veins run transversely from the midrib to the sides: the male flowers come out in long bunches from the axils of the leaves: the female flowers in loose bunches on pretty long red peduncles: the berries are blue, in red cups, growing two and sometimes three together. It is a native of America.

The seventh species is very near akin to the ninth, from which it differs in the leaves, those of the latter having three ribs running longitudinally from the foot-stalk to the point, where they soon diminish; whereas in this the

ribs are small and extend towards the sides; their surface is smooth and shining: they are male and hermaphrodite in different trees: it is a large tree, with ascending branches: the leaves quite entire, smooth, mostly alternate, but some opposite, petioled, whitish underneath: the flowers white, on simple, long, lateral peduncles: the berry small, ovate, dusky or brownish red. It is a native of China, &c. Its wood is in much esteem for carpenters' purposes, being easily wrought, light, durable, and not liable to be injured by insects, particularly the *coombang*, a species of bee, which, from its faculty of boring timber for its nest, is called the *Carpenter*.

The chief of the Camphor used in Europe is prepared from this tree in Japan, by splitting the wood into small pieces, and subliming or distilling it with water in an iron retort, covered with an earthen or wooden head, in the hollow of which they fasten hay or straw, to which the Camphor, as it rises, adheres. This Camphor is brownish or white, but in very small semipellucid grains. It is packed up in wooden casks, and thus sent to India and Europe, where it is purified by a second sublimation, and reduced into the solid mass as found in the shops. Native Camphor, or the *Capoor Barroos* of the Malays, is a production obtained in Sumatra and Borneo by cutting down the trees, and splitting them with wedges into small pieces, the Camphor being found in the interstices in the state of a concrete crystallization. Some have asserted that it is from the old trees alone that this substance is procured, and that in the young trees it is in a fluid state, called *meenio capoor* or Camphor oil; but this is a mistake: the same sort of tree that produces the fluid does not produce the dry, transparent flaky substance, nor ever would. They are readily distinguished by the natives. Many of the trees, however, produce neither the one nor the other. The traders usually distinguish three degrees of quality, by the names of *head*, *belly*, and *foot*, according to its purity and whiteness. Some add a fourth sort, of extraordinary fineness, of which a few pounds only are imported to Canton, and sell there at the rate of two thousand dollars the *pecul*.

The Common Camphor will evaporate till it wholly disappears; while that of Sumatra and Borneo, called *Native Camphor*, though subject to some decrease, does not appear to lose much in quantity from being kept.

Camphor oil is obtained by the Sumatrans by making a transverse incision into the tree, to the depth of some inches, and then cutting slopingly downwards from above the notch, till a

flat horizontal surface be left. This they hollow out, till it is of a capacity to receive a quart: then put into the hollow a bit of lighted reed, and let it remain for about ten minutes, which acting as a stimulus, draws the fluid to that part. In the space of a night the liquor fills the receptacle previously made. The trees are soon exhausted.

The eighth in its native situation is a tree twenty feet high or more, the trunk about six feet high, a foot and a half in diameter, the outer bark smoothish, and of a dusky cinereous colour; it has spreading branches that form an elegant head; but in our stoves it is only of low growth: the leaves are opposite or nearly so, ovate-oblong, oblong-acuminate, or subovate, bluntly acuminate, quite entire, shining, coriaceous, on short petioles, from three to five inches long; the three nerves spring from the petiole, and either immediately recede from each other, or continue united for a line or two and then diverge; they are of a bright green on the upper surface, but pale on the under, with the nerves whitish. On the younger branches or twigs arise slender common peduncles, from opposite axils, the terminating ones an inch, the others two or three inches long, three-flowered at top, or else trifid, with each division three-flowered: the flowers small, greenish yellow, almost insipid, with a somewhat foetid smell: the fruit the form and size of a middling Olive, insipid, deep blue and soft, inclosing a thin, pale-coloured nut with a white kernel, which germinates soon after it falls, and therefore cannot easily be transported to a distance: the inner bark perfectly resembles the Oriental Cinnamon in smell, taste, and figure; the only difference is, that it has a coarser texture, and a more acrid taste, which may arise from the climate. It is a native of Martinico and Brazil, flowering in February and March.

There are several varieties; but it is the Ceylon Cinnamon that is chiefly used as a spice.

The ninth is supposed, according to Martyn, not to be a distinct species from the true Cinnamon. The difference of the bark may, he supposes, be owing to soil or situation, but more probably to want of skill or attention in the cultivators. The Cassia bark is coarser, and will not roll up like true Cinnamon; but the essential difference between the bark of Cinnamon and Cassia is, that the former is always dry, whereas the latter becomes mucilaginous in chewing; hence it has been suggested here, as a conjecture on the most respectable authority, that the superior excellence of Cinnamon bark may be in a great measure owing to its having been deprived of that mucilage which adheres to its interior surface.

Marsden asserts that the Cassia tree grows from fifty to sixty feet high, with large spreading horizontal branches, almost as low as the earth: the leaves are about four inches long, narrower than those of the Bay, and more pointed, deep green, with a smooth surface and plain edge: the principal fibres or nerves take their rise from the peduncle: the young leaves are mostly of a reddish hue: the blossoms grow six in number upon slender footstalks, close to the bottom of the leaf: they are monopetalous, small, white, and stellated in six points: the stamina are six (nine), with one style growing from the germ, which stands up in three brownish segments resembling a cup. It is a native of Malabar.

The bark is commonly taken from such trees as are a foot or eighteen inches in diameter, as when they are younger, it is said to be so thin as to lose all its qualities very soon. Those trees which grow in a high rocky soil have red shoots, and the bark is superior to that which is produced in a moist clay where the shoots are green. Marsden has been assured by a person of extensive knowledge, that the Cassia produced in Sumatra is from the same tree that yields the true Cinnamon, and that the apparent difference arises from the less judicious manner of quilling it. Perhaps the younger and more tender branches should be preferred; perhaps the age of the tree, or the season of the year, ought to be more nicely attended to; and it is suggested, that the mucilage which adheres to the inside of the fresh-peeled rind, when not carefully wiped off, injures the flavour of the Cassia, and renders it inferior to that of the Cinnamon.

The tenth species grows to the height of thirty feet or more in the West Indies, and has a trunk as large as common Apple-trees: the bark is smooth, and of an ash colour: the branches are beset with pretty large, oblong, smooth leaves, like those of Laurel, of a deep green colour, are succulent, and soft. The flowers are for the most part produced towards the extremities of the branches: the fruit is the size of one of our biggest pears, inclosing a large seed with two lobes, included in a thin shell. It is held in great esteem in the West Indies: the pulp is of a pretty firm consistence, and has a delicate rich flavour; it gains upon the palate of most persons, and becomes soon agreeable even to those who cannot like it at first; but it is so rich and mild, that most people make use of some spice or pungent substance to give it a piquancy; and for this purpose, some make use of wine, some of sugar, some of lime-juice, but most of pepper and salt. It is a native of the West Indies.

VOL. II.

Culture.—The first sort may be increased by seed, layers, and suckers.

The seed should be sown soon after the berries are ripe, or early in spring, either in beds, covering them with earth near an inch deep, or in drills half a foot asunder, the same depth: when the plants are come up, they should be supplied with frequent waterings during summer, and in winter defended from severe frost by the shelter of mats, or some other covering, being tender while young; and after having two summers' growth in the seed-bed, in the spring following the strongest should be removed into nursery rows, one or two feet asunder, and a foot apart in each row, giving water in dry weather, till they have taken good root, and keeping them clear from weeds. When they are half a yard, or two or three feet high, they are of proper growth for transplanting into the shrubbery in autumn or spring.

The berries may also be sown in pots, and plunged in a hot-bed in spring, which brings the plants forwarder, being careful to inure them to the full air in the summer season.

Some of the lower branches that are well furnished with young shoots may be laid down in the early spring, or in August, but the latter is the better season; each shoot being slit-layed: they become rooted in one year, when in spring they may be taken off, and planted in the nursery, as directed for the seedlings.

The suckers should be taken up with good roots in autumn or spring, and be planted in the nursery like the seedlings and layers.

It is also capable of growing by cuttings, planted in the beginning of April on a moderate hot-bed of tanners' bark covered eight inches deep with rich loose fresh earth, five inches deep, and eight or nine asunder, rubbing off their leaves, and watering them gently every evening while the bed continues warm, covering the glasses with mats during the heat of the day. When the cuttings have shot roots, they should receive all mild gentle showers, and the evening dews. In the beginning of August, the glasses may be taken off, being replaced when the weather begins to be frosty; keeping them open every mild day. In the beginning of the April following, or as soon as the weather becomes temperate, both glasses and frames should be removed, continuing frequent and plentiful waterings during the summer months, as the weather may require; and in the succeeding April the plants will be strong, well rooted, and fit for planting out.

When the plants raised in these ways are removed to the nursery, they should have their

H

superfluous roots and branches cut away, encouraging the leading shoots; planting them in a well-sheltered quarter of light mould. The ground should be dug over in autumn and spring, keeping it clean, loose, and mellow in summer, and the plants be annually pruned in April.

The gold-striped variety is tender, being commonly kept in pots, and housed with hardy green-house plants. When it stands in the open ground, it is sometimes much injured in severe winters. The method of increasing it is by budding it on the plain sort.

The broad-leaved and narrow-leaved varieties are not so hardy as the common sort, being scarcely able to live abroad whilst young, in common winters, without shelter. As in severe winters the old trees are frequently killed, or at least the branches much injured, the plants are frequently kept in tubs, and housed in winter.

The second, third, and fourth sorts may be increased by seed, by layers, and sometimes by suckers and cuttings. The seeds or berries procured from America, and preserved in sand, should be sown as soon after they arrive as possible, in a bed of light earth an inch deep, or in largish pots the same depth, plunging them in mould, in an eastern border, up to their rims, till the spring following; when they should be placed in a hot-bed, which greatly forwards the germination of the seed, and soon brings up the plants. They must be timely inured to the full air. The plants raised by either method should, while young, be watered during summer, and sheltered from frost in winter, and when two years old be planted out in nursery rows, as directed for the other plants. They may also be increased by layers and suckers in the same manner as directed for the first sort; but it is sometimes long before the layers are rooted.

They are likewise sometimes capable of being increased by cuttings, by the aid of a good hot-bed.

The fifth, sixth, and seventh sorts may be increased by layers, but they are sometimes two years before they are sufficiently rooted. They may also be raised from seeds, procured from the places of their natural growth, sowing them in pots, and plunging them in a hot- or bark-bed; but without this aid they do not always grow freely the first season; in which case they should be placed in the open air in summer, and in a frame or in the green-house, near the windows, in winter; and in spring the pots be plunged in a hot-bed, which will bring up the plants, giving air daily, and frequent waterings, and inuring them by degrees to the open air as the summer advances; placing them in shelter

in winter, and in the following spring planting them out in separate small pots, managing them as other green-house shrubs.

The eighth, ninth, and tenth sorts are also raised by layers and seed, sown and managed as above, generally assisted by the bark-bed of the stove; the plants being planted off into separate pots, and managed afterwards as other hot-house plants.

The first, second, third, and fourth sorts are highly ornamental in the borders and clumps in pleasure-grounds; the three following in green-house collections; and the three last among other stove plants.

LAWN, an open space of short grass-ground, in the front of a residence, or in a garden, park, or other pleasure-ground.

Lawns extended in the principal fronts of habitations, add considerably to the neatness and grandeur of their appearance, by laying them open, and admitting more extensive prospects. Where there is a sufficient scope of ground, they should be as large as the nature of the situation will admit, always being planned in the most conspicuous parts immediately adjoining the houses, and extended outward as far as convenient, allowing width in proportion; having each side or verge bounded by elegant shrubbery compartments in a varied order, separated in some parts by intervening spaces of grass-ground, of varied dimensions, and serpentine gravel-walks, gently winding between and through the plantations, for occasional shady, sheltered, and private walking; or similar walks carried along the fronts of the boundary plantations, and immediately adjoining the Lawns, for more open and airy walking in; and in some concave sweeps of the plantations there may be recesses and open spaces both of grass and gravel, of different forms and dimensions, made as places of retirement, shade, &c.

The usual situations of Lawns are those just mentioned; but if the nature of the ground admit, or in cases where there is good scope of ground, they may be continued more or less each way; but always the most considerably on the principal fronts, which if they be to the south, or any of the southerly points, they are the most desirable for the purpose.

The dimensions may be from a quarter of an acre or less, to six or eight acres or more, according to the extent and situation of the ground. Sometimes Lawns are extended over ha-has, to ten, twenty, or even to fifty or sixty acres or more.

The form must be directed by the nature of the situation; but it is commonly oblong, square, oval, or circular. But in whatever figure they

are designed, they should widen gradually from the house outward to the furthest extremity, to have the greater advantage of prospect; and by having that part of them within the limits of the pleasure-ground, bounded on each side by plantations of ornamental trees and shrubs, they may be continued gradually near towards each wing of the habitation, in order to be sooner in the walks of the plantations, under shade, shelter, and retirement. The terminations at the further ends may be either by ha-has to extend the prospect, or by a shrubbery, or plantation of stately trees, arranged in sweeps and concave curves. But where they extend towards any great road, or distant agreeable prospect, it is more in character to have the utmost verge open, so as to admit of a grand view from and to the main residence.

The side-boundary verges should have the plantations rurally formed, airy, and elegant, by being planted with different sorts of the most ornamental trees and shrubs, not in one continued close plantation, but in distinct separated compartments and clumps, varied larger or smaller, and differently formed, in a somewhat natural imitation, being sometimes separated and detached less or more, by intervening breaks and open spaces of short grass, communicating both with the Lawns and interior districts; and generally varied in moderate sweeps and curves, especially towards the Lawns, to avoid stiff, formal appearances, both in the figure of the Lawns and plantations. In planting the trees and shrubs, which should be both of the deciduous and evergreen kinds, where intended to plant in distinct clumps, either introduce the deciduous and evergreens alternately in separate parts, or have some of both interspersed in assemblage; in either method placing the lower growth of shrubs towards the front, and the taller backwards in proportion to their several statures, so as to exhibit a regular gradation of height, that the different sorts may appear conspicuous from the main Lawns. They may be continued backwards to a considerable depth, being backed with trees and shrubs of more lofty growth. The internal parts of the plantations may have gravel or sand walks, some shady, others open; with here and there some spacious short grass openings of different dimensions and forms.

Extensive Lawns in parks or paddocks, &c. have seldom any boundary plantations close to what may be considered as a continuation of them beyond the pleasure-ground, but are sometimes dotted with noble trees, dispersed in various parts, at great distances, so as not to obstruct the view; some placed singly, others in groups by twos, threes, fives, &c. and some placed irregularly, in triangles, sweeps, straight lines,

and other different figures, to cause the greater variety and effect, each group being diversified with different sorts of trees, all suffered to take their natural growth.

These kind of spaces or openings should always be kept perfectly neat, by being often mowed, rolled, and mown. See GRASS-GROUND, and TURFING.

LAWSONIA, a genus containing plants of the exotic tree kind for the stove.

It belongs to the class and order *Octandria Monogynia*, and ranks in the natural order of *Salicarieæ*.

The characters are: that the calyx is a four-cleft perianthium, small, permanent: the corolla has four petals, ovate-lanceolate, flat, spreading: the stamina have eight filiform filaments, length of the corolla, in twin pairs between the petals: anthers roundish: the pistillum is a roundish germ: style simple, length of the stamens, permanent: stigma headed: the pericarpium is a capsule (or berry), globose with a point, four-celled: the seeds many, cornered and pointed.

The species are: 1. *L. inermis*, Smooth Lawsonia; 2. *L. spinosa*, Prickly Lawsonia.

The first rises with a shrubby stalk eight or ten feet high: the branches come out by pairs opposite; they are slender and covered with a whitish yellow bark: the leaves are small, opposite, oblong, ending in acute points, pale green: the flowers in loose terminating bunches, gray or dirty white: the petals small, turning back at the top. It is a native of India, &c.

The second species rises with a woody trunk eighteen feet high or more: the wood is hard and close, covered with a light gray bark: the branches alternate: the leaves oblong-oval: at the joints where the leaves are placed come out single, strong, sharp thorns: the flowers are in loose bunches from the sides of the branches, pale yellow, of a disagreeable scent. It is a native of the East Indies.

Culture.—These plants may be raised by sowing the seeds in pots of light mould in the early spring, plunging them in the bark-bed of the stove. When the plants have acquired a few inches growth, they should be removed into separate small pots filled with light sandy earth, replunging them in the bark-bed, and giving a little water, with proper shade. They afterwards may be placed so as to have pretty free air, but be constantly kept in the stove.

They afford variety among other stove plants.

LAYER, the young shoot or branch of such trees as are capable of being raised by being laid into the ground. It is the part which is placed in the earth in order to strike root.

LAYING, the operation of placing layers in the soil. It is a method adapted to most sorts

of trees and shrubs, and many herbaceous plants. It is effected by laying branches and young shoots of trees and plants in the earth, from two or three to five or six inches deep, leaving their tops out, that the part layed in the earth may emit roots, and become a plant. The layers, when rooted, should be separated from the parent, and planted in the nursery, or other proper place, to acquire due strength and size, for the purposes for which they are designed.

They require different lengths of time for becoming rooted, from a few months to two or more years.

Numbers of shrubs and trees are increased by layers, but the practice is more particularly applicable to the shrub kind; as their branches grow near the ground, convenient for being laid down. It may, however, be practised with success on fruit-trees and forest-trees, when their branches are situated low enough for being laid, though the varieties of many fruit-trees are better propagated by grafting and inoculation. The vine and fig, however, often admit of being increased by layers; and forest-trees, for the continuance of varieties; as the plants raised in this method continue exactly the same as the parent plant from whence they were raised. This is a certain method to continue any approved variety, as well as to increase such shrubs or trees as do not produce seeds here, and which cannot be easily obtained. It is likewise an expeditious and easy mode of propagation; as by it many new plants are often raised in a few months, which would take two or three years to bring them to the same size from seed. In many sorts it is so easy that all the shoots of any branch situated near the ground, or convenient for laying down, may be made distinct plants.

For all sorts of the tree or shrub kinds, it is generally performed on the young shoots of the preceding summer, which should be laid down in spring or autumn; but sometimes on shoots of the same year, in summer, especially in the hard-wooded evergreen trees and shrubs, that do not strike root readily in the older wood. Many sorts of trees that have their wood of a soft loose texture often grow pretty freely by Layers of them, of two or several years growth.

In herbaceous plants capable of being propagated by layers, such as carnations, pinks, double sweet-williams, &c. the young shoots of the same year, laid down in June and July, are commonly the most successful.

The season for performing this sort of work, in most sorts of trees and shrubs, is autumn and spring, though it may be performed at almost any time of the year.

Many kinds of under-shrubby and herba-

ceous plants also succeed, if layed any time in spring or summer till the end of June; though that and the following month are the most successful for the herbaceous tribe, as carnations and others usually propagated by laying, as they then root the same season in from three or four to five or six weeks, so as to be proper for transplanting.

When it is intended to lay trees or shrubs that naturally run up to stems, without furnishing any considerable quantity of lower branches for laying, a sufficient number of strong plants should be set in the nursery, at proper distances, and headed down in the autumn or spring after, within a few inches of the ground, that they may throw out a good quantity of young shoots the following summer, near the earth, so as to be convenient for laying down in the succeeding autumn; or, by waiting another year many more shoots for the purpose of layers will be provided, by the first shoots throwing out many lateral ones, each of which when layed will form a plant. And on the layers being rooted, and all cleared away, the stool remaining will furnish another crop of shoots for laying next year, and the same in succession for many years.

When layers are wanted from trees that are grown up, and whose branches are at a distance from the ground, a temporary stage or scaffold is erected, on which pots or tubs of mould are placed to receive the layers.

The general method of merely laying the branches or shoots in the earth, is practised for all sorts; but previous to laying, they are often prepared in different ways to facilitate their rooting, according as the trees of different natures require; as by simple laying, twisting, slitting, cutting the bark, piercing the shoot, wiring, &c.

Simple Laying.—This is merely laying the shoots in the earth, as directed below, without any previous preparation of twisting, slitting, &c. and is sufficient for a great number of trees and shrubs of the soft-wooded kinds; but for such as do not readily root by this simple method, recourse must be had to some of the following ways.

Twisting the Layer.—By giving the shoot a gentle twist in the part designed to be layed in the ground, it greatly promotes and facilitates the emission of fibres from the bruised part.

Slitting or Tonguing the Layer.—This is the most universal and successful mode, where any preparation of the shoot is necessary to promote its rooting; it is performed by slitting the shoot at a joint underneath, up the middle, half an inch or an inch or more long, according to the size and nature of the layer, forming a sort of tongue nearly the same as directed for

ernation layers; laying that part in the earth, and raising the top upright, or rather pointing inwards, so as to separate the tongue of the slit from the other part, and keeping the slit open, as directed below.

Cutting the Bark.—This is performed by cutting the bark all round at a joint, taking out small chips all the way below the cut, and laying that part in the earth, by which it readily emits roots.

Piercing the Layer.—This is done by thrusting an awl through the shoot, at a joint, in several places, laying that part in the ground, by which it will emit fibres from the wounds more readily.

Wireing the Layer.—This is by twisting a piece of wire hard round the shoot at a joint, and pricking it with an awl on each side of the wire in several places, laying it in the earth, by which it breaks out into roots at the confined and wounded parts; often proving successful in such trees and shrubs as do not readily emit fibres by the other methods.

By some of these methods almost all sorts of trees and shrubs may be propagated.

The general method of laying all sorts of trees or plants, either by simple laying, or any of the other methods, is the following.

The ground about each plant must be dug for the reception of the layers, making excavations in the earth to lay down all the shoots or branches properly situated for the purpose, pegging each down with a hooked stick, laying also all the proper young shoots on each branch or main shoot, fixing each layer from about three or four to six inches deep, according as they admit, and directly moulding them in that depth, leaving the tops of every layer out of ground, from about two or three to five or six inches, according to their length, though some shorten their tops down to an eye or two only above the earth, raising the top of each layer somewhat upright, especially the slit or tongued layers, to keep the slit part open. As all the layers of each plant or stool are thus laid, all the mould should be levelled in equally in every part, close about every layer, leaving an even smooth surface, with the top of each layer out.

It sometimes happens that the branches of trees are so inflexible as not to be easily brought down for laying; in which case they must be plashed, making the gash or cut on the upper side; and when they are grown too large for plashing, or the nature of the wood will not bear that operation, they may be thrown on their sides, by opening the earth about the roots, and loosening or cutting all those on one side, that the plant may be brought to the ground,

to admit of the branches being laid down into the earth.

When layers are to be made from green-house shrubs, or other plants in pots, the work should generally be performed in pots, either in their own, or others placed for that purpose.

After laying in either of the above methods, there is no particular culture necessary, except in the heat of summer giving occasional waterings to keep the earth moist about the layers, which will greatly forward them, and promote a good supply of roots against autumn, when those that are properly rooted should be taken off and transplanted.

The layed branches or shoots should be examined at the proper season, October and November, and those that are rooted be cut from the mother plant, with all the root possible, planting them out in nursery rows, a foot or two asunder, according to their nature of growth, there to remain till of due size for their several purposes; but those of the tender kinds must be potted, and placed among others of similar nature and growth.

When the layers are all cleared from the stools or main plants, the head of each stool, when to be continued for furnishing layers, should be dressed; cutting off all decayed and scraggy parts, digging the ground about them, working some fresh mould in close about their heads, to refresh and encourage their producing a fresh supply of shoots for the following year's laying down.

LEATHERWOOD. See DIRCA.

LEDON. See CISTUS.

LEDUM, a genus containing plants of the hardy evergreen kind. The Marsh Cistus, or Wild Rosemary.

It belongs to the class and order *Decandria Monogynia*, and ranks in the natural order of *Bicornes*.

The characters are: that the calyx is a one-leaved perianthium, very small, five-toothed: the corolla one-petalled, flat, five-parted: divisions ovate, concave, rounded: the stamens have ten filiform filaments, spreading, length of the corolla: anthers oblong: the pistillum is a roundish germ: style filiform, length of the stamens: stigma obtuse: the pericarpium is a roundish capsule, five-celled, gaping five ways at the base: the seeds numerous, oblong, narrow, sharp on each side, extremely slender.

The species cultivated is *L. palustre*, Marsh Ledum.

It has a branched root, running widely and deeply into the ground: the stems are shrubby, slender, three or four feet long, dividing into simple branches, and covered with a brown bark, which is tomentose or villose whilst they

are young, but afterwards becomes smooth: the leaves are linear-lanceolate, dusky green above, and smooth, underneath covered with a brown pile, quite entire, resembling those of Rosemary, but wider, petioled, and perennial: the flowers are on peduncles an inch or more in length, nodding before and after flowering, whitish, in axillary bundles or corymbs: the capsule small, obovate, terminated by a long permanent style: valves coriaceous: partitions membranaceous, springing from the edges of the valves, doubled, opening at their inner angle by a longitudinal chink: the receptacles five, filiform, curved a little, springing from the upper part of the axis of the fruit, and hanging down freely in the cavity of the cells. It is a native of the north of Europe, flowering in April and May.

It varies with erect and decumbent branches.

Culture.—These plants are increased by sowing the seeds in pots filled with boggy earth, or in shady borders of the same kind of mould, in the spring season.

But the best method is to take up the plants in their native situations, with balls of earth about their roots, and plant them in borders of the above kind, keeping them well watered.

Layers of the young shoots sometimes will grow.

They afford variety in shady situations, where the soil is of the boggy kind.

LEEKS. See ALLIUM.

LEMON TREE. See CITRUS.

LEPIDIUM, a genus containing a plant of the herbaceous annual kind.

It belongs to the class and order *Tetradynamia Siliculosa*, and ranks in the natural order of *Siliculosæ* or *Cruciformes*.

The characters are: that the calyx is a four-leaved perianthium: leaflets ovate, concave, deciduous: the corolla four-petalled, cross-shaped: petals obovate, twice the length of the calyx, with narrow claws: the stamens have six awl-shaped filaments, length of the calyx, the two opposite ones shorter: anthers simple: the pistillum is a heart-shaped germ: style simple, length of the stamens: stigma obtuse: the pericarpium is a silicle, heart-shaped, emarginate, compressed, sharp on the margin, two-celled: valves navicular, keeled, opposite the lanceolate dissepiment: the seeds ovate-acuminate, narrower at the base, nodding.

The species cultivated is *L. sativum*, Garden or Common Cress.

Other species may be cultivated for variety.

It has an annual, white, fusiform, slender root: the stem upright, round, smooth, from a foot to two feet in height, branched at top: both stem and branches terminated by loose narrow spikes of flowers: the leaves oblong, al-

ternate, pinnate, the pinnas of the lower multifid, of the upper more entire, linear or lanceolate: the flowers small: the calyx very small, greenish: the petals white, larger than the calyx: the silicle roundish, without any style: the valves winged: the seeds small, rufescent, ovate, marked with lines, having a sharp taste like Mustard. Its native place is unknown.

There are several varieties, as with broad leaves, with curled leaves, and the common sort with the leaves multifid.

Culture.—These plants are raised by sowing the seed as wanted for use, at different times of the year, as once a week or fortnight, where a constant succession of small herbs in their young growth is wanted for sallads, when only a few days or a week or two old; or where a constant supply of those small herbs are required in their young seedling growth, some should, as has been observed, be sown in succession every week or fortnight at furthest, all spring, summer, and autumn; and once a fortnight in the winter season.

The order of sowing them in the different seasons is; in a warm south border or other similar situation, or under a frame, &c. in the early spring months; and as the warm season advances, in any open compartment, all in as light earth as the garden affords; but in summer, or hot dry weather, in somewhat shady borders, or in a free situation, shaded with mats from the scorching sun, and daily watered; and in winter in the warmest situation, or in shallow frames defended with lights, and under hand glasses: but in frosty or other very cold weather, in that season, on moderate hot-beds; and hot-bed sowings are also requisite during the colder part of the spring, or at any time in cold seasons, where a supply of these and other small-sallad herbs are required to be raised as quickly as possible.

The method of sowing the seed in all cases is very thick, as the plants are mostly used in small young growth, and mostly in small, flat, shallow drills, about three inches asunder, so thick as almost to cover the earth, being lightly earthed over a quarter of an inch thick, or less; or on the plain surface, first raking it smooth, then sowing the seed thick as above, smoothing it down with the back of the spade, and either with the spade spreading some fine earth lightly over it as thinly as possible, or covering it by sifting earth over it evenly a small depth, just to cover all the seed properly. This sort of sallad herb should always be cultivated so as to grow as rapidly as possible, being cut while perfectly young. See SMALL SALLAD HERBS.

LETTUCE. See LACTUCA.

LEUCOJUM, a genus containing plants of the bulbous-rooted flowery perennial kind.

It belongs to the class and order *Hexandria Monogynia*, and ranks in the natural order of *Spathaceæ*.

The characters are: that the calyx is an oblong, obtuse, compressed spathe, gaping on the flat side, withering: the corolla is bell-shaped-expanding: petals six, ovate, flat, conjoined at the base, with the tips thickish and stiffish: the stamina have six setaceous filaments, very short: anthers oblong, obtuse, quadrangular, upright, distant: the pistillum is a roundish inferior germ: style clavate, obtuse: stigma setaceous, upright, sharp, longer than the stamens: the pericarpium is a top-shaped capsule, three-celled, three-valved: the seeds several, roundish.

The species cultivated are: 1. *L. vernum*, Great Spring Snow-drop; 2. *L. æstivum*, Summer Snow-drop; 3. *L. autumnale*, Autumnal Snow-drop; 4. *L. strumosum*, Many-flowered Cape Leucojum.

The first has an oblong bulb, shaped like that of the Daffodil, but smaller: the leaves are flat, deep green, four or five in number, broader and longer than those of the Common Snow-drop: the scape angular, near a foot high, hollow and channelled: towards the top comes out a whitish sheath, opening on the side, out of which come out two or three flowers, hanging on slender peduncles: the corolla is much larger than that of the Common Snow-drop; and the ends of the petals are green. They appear in March, and have an agreeable scent, not much unlike those of the Hawthorn.

The flowers, which at first sight resemble those of the Common Snow-drop, are easily distinguished by the absence of the Three-leaved Nectary: they do not come out so soon by a month. It is called by Mr. Curtis, *Spring Snow-flake*. It is a native of Italy, &c.

The second species has a bulb the size of a Chestnut, somewhat ovate, outwardly pale brown, inwardly white; coats numerous, thin, and closely compacted. But Miller asserts, that it is nearly as large as that of the Common Daffodil, and very like it in shape: that the leaves also are not unlike those of the Daffodil, more in number than in the first, and keeled at the bottom, where they fold over each other, and embrace the stalk: the leaves are about a foot and half in length, upright, nearly linear, almost an inch in breadth, obtuse; the lower ones shortest: the scape a little higher than the leaves, hollow, slightly flattened, two-edged, a little twisted, one side sometimes obtuse, the other acute: the peduncles for the most part five from the same sheath, each supporting a single flower, angular, and of un-

equal lengths: the flowers are pendulous, growing all one way, having little scent: the petals are white, finely grooved within, not at all uniting at bottom; the tips thickish, a little puckered, and marked with a green spot. The flowers appear at the end of April or the beginning of May, and there is a succession of them during three weeks, or longer in cool weather. It is a native of Hungary, &c.

To distinguish it from *Galanthus*, Mr. Curtis names it *Summer Snow-flake*; and in gardens it is known by the name of *Great Summer Snow-drop*; *Late* or *Tall Snow-drop*.

The third has a thick bulb for the size of the plant, composed of many glutinous coats, bitter, covered with a whitish membrane: the scape slender, brownish, a hand in height, supporting two or three small white flowers (sometimes only one), hanging down, having no smell. It is distinguished by its four or five capillary leaves; which begin to spring up after the flower is past, when the seeds are ripening, and sometimes after the heads are ripe. They abide all the winter and spring following, and wither away in the beginning of summer; leaving the scape to appear naked: the flowers are a little reddish at the bottom next the stalk. It is a native of Portugal, flowering in September.

The fourth has a roundish white bulb, less than a hazel nut: the leaves two or three, inclosed at the base in a white sheath, filiform, dotted with white, keeled at bottom, flat, or a little convex on the back, weak, and more or less lying on the ground: scape flexuose-erect, slender, about half a foot high, roundish, terminated by a spreading umbel of from three to seven flowers: the valves of the spathe lanceolate, acute, membranaceous, opposite, sometimes equal, sometimes not, pale: the peduncles filiform, one-flowered, unequal, from one to two inches in length: flowers without scent, coming out successively: petals white within, purplish without, oblong, lanceolate, three lines in length; the three inner bluntish; the three outer acute, with a blunt, greenish keel: anthers purple: germ three-cornered, green: style white, swelled out at bottom into a body larger than the germ, plaited at bottom; thence awl-shaped, bluntly three-cornered, the length of the stamens: stigma obscurely trifid: capsule subglobular, three-cornered: the whole plant is smooth. It is a native of the Cape, flowering in November.

Culture.—These plants are readily increased by off-sets from the roots, which should be separated from the old roots about every third year, in the summer season, as soon as their leaves begin to decay, in the same manner as other bulbous roots. See **BULBOUS ROOTS**.

They may also be increased by seeds, which should be sown in the latter end of August, in a border of light bog earth. The plants should remain in this situation till the second summer, and be then taken up at the proper period and planted in beds, till they begin to flower, when they should be removed into the borders. In this way they are three or four years before they flower.

The best method is, to procure the roots from the nurserymen, and plant them in the beginning of the autumn, in an eastern or northern border, where the soil is of a boggy quality, in patches of three or four together, in the fronts, putting them in to the depth of about three or four inches.

The off-sets should be planted out in beds a year or two after being taken off, till fit to be set out for flowering.

A soft loamy soil, or a mixture of loam and bog earth, are the most suited to their healthy growth. The last sort requires protection in the house with other Cape bulbs.

By planting them in the different aspects mentioned, a longer succession of flowers may be produced.

They are very ornamental in the fronts of the borders, or the sides of the lawns, and other parts near the house.

LIGHT, a subtle fluid highly necessary to the healthy growth and vigour of plants.

The author of the *Philosophy of Gardening* remarks, that the contest for light as well as for air, which is so visible in the growth of vegetables, shows the former to be of great consequence to their existence, as well as the latter. "Thus," says he, "many flowers follow the sun during the course of the day, by the nutation of the stalks, not by the rotation of them, as observed in the Sun-flower, by Dr. Hales, and the leaves of all plants endeavour to turn their upper surfaces to the light, which is their respiratory organ, or lungs. The great use of all plants turning the upper surfaces of their leaves to the light, is thus rendered intelligible; the water perspired from those surfaces is, he conceives, hyperoxygenated; and, as it escapes from the sharp edges of the mouths of the perspiring vessels, when acted upon by the sun's light, gives out oxygen; which oxygen thus liberated from the perspired water, and added to that of the common atmosphere, presents to the respiratory terminations of the pulmonary vessels on the upper surfaces of leaves, an atmosphere more replete with vital air. This necessity of light to the respiration of vegetables is so great, he thinks, that there is reason to believe that many plants do not respire during the night, but exist in a torpid state, like winter-

sleeping insects. Thus the *Mimosa*, Sensitive Plant, and many others, close the upper surfaces of their opposite leaves together during the night, and thus preclude them both from the air and light; and the internal surfaces of innumerable flowers, which are their respiratory organs, are closed during the night, and thus unexposed both to light and air.

"It is however observed, that the *fungi*, which are termed vegetables because they are fixed to the earth, or to the stones, or trees, or timber, where they are found, can exist without light, or much air, as appears in the truffle, which never appears above ground; and by other *fungi*, which grow in dark cellars; and in esculent mushrooms, which are cultivated beneath beds of straw."

The etiolation or blanching of vegetables also depends upon keeping the light from them.

It is further contended, that "the element of light, as well as that of heat, is necessary to vegetation. In this climate they both seem in general to be injurious only by their defect, and seldom by their excess. But as light acts as a stimulus on the more irritative or sensitive parts of plants, which appear by the expansion of many flowers, and of some leaves, when the sun shines on them, and by the nutation of the whole flower, as of the Sun-flower (*Helianthus*), and by the bending of the summits of all plants confined in houses towards the light; there may be diseases owing to the excess of this stimulus, which have not been attended to; to prevent which, the flowers of *Tragepogon*, *Salsafi*, and of other plants, close about noon. Other unobserved diseases may be owing to a defect of the stimulus of light; as a *Mimosa*, Sensitive Plant, which had been confined in a dark room, did not open its foliage, though late in the day, till many minutes after it was exposed to the light." The excess of light has not, however, been observed to be attended by vegetable diseases in these more northern latitudes.

Experience has shown its infinite service to the growth of vegetables, contributing exceedingly to facilitate their vegetation, and increase their perfection and duration; as it is obvious that most plants are considerably more prosperous, and attain greater perfection, in a free exposure fully open to the light and air, than in shady places; the same is observed of fruits. Those growing in a situation full to the light of the sun, are in general more large and fair, ripening sooner, and more perfectly, as to beauty and richness of flavour, than such as grow in the shade: these reasons should therefore determine us to cultivate most of the principal plants and fruits in situations open as much as possible to the full light and influence of the

sun; though upon particular occasions, in the heat of summer, shady places may be necessary for some sorts of plants; though not where shaded and darkened by spreading trees, &c. but a border open above to the full light, and only shaded from the immediate rays of the sun. For the general crops, a perfectly open, sunny, light situation, free from the shade of spreading trees, is always the most proper.

Its utility is very evident, from plants growing in garden-frames, green-houses, &c. in winter, when, in time of severe weather, covers or shutters have been continued long over the glasses, so as to exclude the rays of light, becoming sickly, growing pale, and assuming an unhealthy appearance for a long time; the leaves often either decaying or dropping off; and frequently when the covers are continued very long without the admission of light, the whole plant in many sorts gradually dwindles and perishes. Great attention is of course requisite in this case, when, from the severity of the weather, the use of other covers besides the glasses is necessary, to take every opportunity of a favourable day, or even an hour or two of a day, to admit the light as fully as possible.

The same is also the case with plants in early hot-beds, such as Cucumbers, Melons, &c. which, early in the year, require a covering of mats over the glasses every night; as when these additional covers are applied too soon in the afternoon, and continued late in the morning, so as to keep the plants long in darkness, it is highly disadvantageous to their growth, causing them to grow weak, pale, and sickly.

As light is, therefore, so beneficial to plants in general, it should be increased as much as possible to those in frames, green-houses, stoves, &c. In these situations it may be useful to paint the inside of all such departments white, to reflect the rays of light as much as possible, and particularly in the nights, and in day-time when the severity of the season requires covers or shutters to be placed over the glasses.

LIGHTS, a term applied to the moveable glazed sashes which cover garden-frames; and which, according to the number of lights, or separate moveable glasses, are denominated one-light, two-light, and three-light frames; these being the general different sizes of garden-frames. See **FRAME**.

LIGUSTICUM, a genus containing plants of the herbaceous, biennial, and perennial kinds.

It belongs to the class and order *Pentandria Digynia*, and ranks in the natural order of *Umbellatae* or *Umbelliferae*.

The characters are: that the calyx is an universal umbel, manifold: partial manifold:
Vol. II.

involucre universal membranaceous, seven-leaved, unequal: partial scarcely four-leaved, membranaceous: perianthium proper five-toothed, obscure: the corolla is universal uniform: florets all fertile: proper of five petals, which are equal, involute, flat, entire, inwardly keeled: the stamina have five capillary filaments, shorter than the corolla: anthers simple: the pistillum is an inferior germ: styles two, approximated: stigma simple: there is no pericarpium: fruit oblong, cornered, five-furrowed, bipartite on each side: the seeds two; oblong, smooth, marked on one side with five elevated striae, flat on the other side.

The species cultivated are: 1. *L. levisticum*, Common Lovage; 2. *L. Scoticum*, Scotch Lovage; 3. *L. Austriacum*, Austrian Lovage.

The first has a strong, fleshy, perennial root, striking deep into the ground, and composed of many strong fleshy fibres covered with a brown skin, and having a strong hot aromatic smell and taste: the leaves are large, composed of many leaflets shaped like those of Sniallage, but larger, and of a deeper green: the stems six or seven feet high, large and channelled, dividing into several branches, each terminated by a large umbel of yellow flowers. It is a native of the Alps of Italy, &c. flowering in June and July, and the seeds ripening in autumn.

The second species has a biennial root, (perennial) of much less size than the preceding: the leaflets are broader and shorter; each leaf having two or three ternate leaflets, indented on their edges: the stalk rises about a foot high, and sustains a small umbel of yellow flowers, shaped like those of the preceding. It is a native of Scotland, North America, &c.

The third has a root half a foot long or more, the thickness of the human thumb, often branched, yellowish brown on the outside, pale within and spongy: the stem upright, from two to three feet in height, grooved, hollow without any partitions at the joints, the whole leafy, as thick as the thumb or finger, simply branched at top only: the root-leaves very large; the stem-leaves above the middle sessile: the leaflets of the general involucre lanceolate, acute, pale green with a whitish membranaceous edge, about half the length of the umbel, reflex, entire, or variously gashed; of the partial involucre about six, all commonly quite entire, the outer equalling the umbellets, and not bent back: terminating umbel of about forty rays, from four to seven inches in diameter: the rest much smaller; all close: these, which are at the tops of the branches, flower later, and gradually exceed the primary umbel in height, surrounding it when in fruit: the flowers are strong-

smelling, large, all fertile. It is a native of Austria, &c. flowering from June to August.

Culture.—These plants are increased by sowing the seeds either in the places where they are to remain, or in beds of light earth, in the autumn or spring, but the former is the better method, raking them lightly in. When the plants have attained a few inches growth, they should be removed from the beds into other beds, where the soil is moist, and set out two feet apart each way, and in the autumn those for the border removed into them; but the above is the better practice.

The plants sown where they are to grow, should be thinned out in the spring, and be kept clean from weeds.

They may be admitted in large borders for the purpose of variety. The first is also used as a medicinal plant.

LIGUSTRUM, a genus containing a plant of the hardy deciduous and evergreen shrubby kind—Privet.

It belongs to the class and order *Diandria Monogynia*, and ranks in the natural order of *Sepiariae*.

The characters are: that the calyx is a one-leaved, tubular perianthium, very small: mouth four-toothed, erect, obtuse: the corolla one-petalled, funnel-form: tube cylindric, longer than the calyx: border four-parted, spreading: divisions ovate: the stamina have two filaments, opposite, simple: anthers upright, almost the length of the corolla: the pistillum is a roundish germ: style very short: stigma two-cleft, obtuse, thickish: the pericarpium is a globose berry, smooth, one-celled: the seeds four, convex on one side, cornered on the other.

The species cultivated is *L. vulgare*, Common Privet.

It is a shrub, usually about six feet in height, branched, the bark of a greenish ash-colour, irregularly sprinkled with numerous prominent points: branches opposite, the young ones flexible and purplish: the leaves opposite, on very short petioles, smooth on both sides, perfectly entire, the lower ones at the bottoms of the small branches least: the panicle about two inches in length, close and somewhat pyramidal; branches and pedicels appearing villose when magnified: the corolla white, but soon changing to a reddish-brown: the flowers are sweet-scented: berry superior, fleshy, subglobular, shining, of so dark a purple as to seem black: it is found wild in most parts of Europe, &c. flowering in July, and the berries ripening in autumn.

There are several varieties; as with the leaves in threes and enlarged at the base, with silver-striped leaves, with gold-striped leaves, with white berries; and Evergreen or Italian Privet, which

rises with a stronger stem, the branches less pliable, and grows more erect; the bark is of a lighter colour; the leaves much larger, ending in acute points, of a brighter green, and continue till they are thrust off by the young leaves in the spring: the flowers are rather larger, and are not often succeeded by berries in this climate.

The chief use of the common sort is to form such hedges as are required in dividing gardens for shelter or ornament; and for this the Italian or Evergreen kind is usually preferred: it bears clipping well, is not liable to be disfigured by insects, and having only fibrous roots, it robs the ground less than almost any other shrub: it is one of the few plants that will thrive in the smoke of large towns, though it seldom produces any flowers in the closer parts after the first year: it also grows well under the drip of trees and in shade: the *Sphinx Ligustri*, or Privet Hawk Moth, and *Phalaena Syringaria*, feed on it in the caterpillar state, and *Meloe vesicatorius*, *Cantharides* or Blister Beetle, is found on it. From the pulp of the berries a rose-coloured pigment may be prepared: with which, by the addition of alum, they dye wool and silk of a good durable green: for which purpose they must be gathered as soon as they are ripe.

Culture.—These plants are capable of being increased by seed, layers, suckers, and cuttings; but the first method affords the best plants: the seed should be sown in autumn, in a bed of common earth an inch deep, or in drills the same depth; but as they do not always grow freely the first year, they may be buried till next autumn, in pots of sandy earth, in the ground, and then sown as above: when the plants come up they should be kept well weeded, and, when a year or two old, be planted out in nursery-rows, to remain two or three years, then removed where they are wanted to remain: the layers should be laid down, from some of the pliable young branches, in the earth, in autumn or winter, when they will be well rooted by the autumn following; then take them off from the stool, with their roots, and plant them in the nursery for a year or two, or till of proper size for the purposes they are intended for: the suckers which rise annually from the roots should be taken up in autumn, winter, or spring, with roots, and planted in the nursery as above: the cuttings of the young shoots, eight or ten inches long, should be planted in the autumn, in a shady border, where they will be properly rooted by the following autumn, when they may be planted out in nursery rows, to acquire proper growth, in the manner directed above. The varieties with striped leaves may be increased by budding, or inarching, upon the plain

sort; or by laying down the branches,—but they seldom shoot so fast as to produce branches proper for this purpose; and being more tender, they should have a dry soil and a warm situation: in a rich soil they soon lose their variegation, and become plain. The Italian or Evergreen sort, which is now generally found in the nurseries, is equally hardy, and thrives in almost any situation: it is increased in the same manner; but as it seldom produces berries in this climate, they must be procured from the place of its native growth.

The plants, besides their use as above, may be introduced in the shrubberies and other parts, by way of variety, especially the Evergreen sort.

LILAC. See *SYRINGA*.

LILIUM, a genus containing plants of the bulbous-rooted flowery perennial kind.

It belongs to the class and order *Hexandria Monogynia*, and ranks in the natural order of *Coronariæ*.

The characters are: that there is no calyx: the corolla is six-petalled, bell-shaped, narrowed beneath: petals upright, incumbent, obtusely carinated on the back, gradually more expanding, wider; with thick, reflex, obtuse tips: nectary, a longitudinal, tubular line, engraven on each petal from the base to the middle: the stamina have six awl-shaped filaments, upright, shorter than the corolla: anthers oblong, incumbent: the pistillum is an oblong germ, cylindric, striated with six furrows: style cylindric, length of the corolla: stigma thickish, triangular: the pericarpium is an oblong six-furrowed capsule, with a three-cornered, hollow, obtuse tip, three-celled, three-valved; the valves connected by hairs disposed in a cancellated manner; the seeds are numerous, incumbent in a twin order; flat, outwardly semi-orbicular.

The species cultivated are: 1. *L. candidum*, Common White Lily; 2. *L. Catesbæi*, Catesby's Lily; 3. *L. bulbiferum*, Bulb-bearing or Orange Lily; 4. *L. Martagon*, Purple Martagon Lily, or Turk's Cap; 5. *L. Pomponium*, Pomponian Lily; 6. *L. chalcedonicum*, Scarlet Martagon Lily; 7. *L. superbum*, Great Yellow Martagon Lily; 8. *L. Canadense*, Canada Martagon Lily; 9. *L. Camschatcense*, Kamtschatka Lily; 10. *L. Philadelphicum*, Philadelphian Martagon Lily.

The first has a large bulb, from which proceed several succulent fibres: the stem stout, round, upright, usually about three feet in height: the leaves numerous, long, narrow-pointed, smooth, sessile: the flowers large and white, terminating the stem in a cluster on short peduncles: the petals within of a beautiful shining white;

on the outside ridged and less luminous. It is a native of the Levant, flowering in June and July.

The principal varieties are; with striped flowers, or with blotched purple flowers, or with variegated striped leaves, or with yellow-edged leaves, with double flowers, and with pendulous flowers.

The first of these varieties is now become common; but the purple stain giving the flower a dull colour, the common white is generally preferred: the second is chiefly valued for its appearance in winter and spring; for the leaves coming out early in the autumn, spreading themselves flat on the ground, and being finely edged with a broad yellow band, make a pretty appearance during the winter and spring months, as it flowers earlier than the plain sort: the third is of little value, as the flowers never open well unless they are covered with glasses, nor have they any of the rich odour of the common sort: the fourth came originally from Constantinople; the stalk is much more slender; the leaves narrower and fewer in number; the flowers not quite so large, and the petals more contracted at the base; they always hang downwards; the stalks are sometimes very broad and flat, appearing as if two or three were joined together: when this happens, they sustain from sixty to one hundred flowers, and sometimes more; this however is merely accidental, as the same root scarcely ever produces the same two years together.

The second species is one of the least of the cultivated sorts, the whole plant when in bloom being frequently little more than a foot high; in its native soil it is described as growing to the height of two feet: the stalk is terminated by one upright flower: it is purple, slender, upright, round, smooth with a slight glaucous bloom on it, solid, stiffish: the root-leaves few, often only on the barren plant, on long petioles: the stem-leaves are numerous, alternately scattered, sessile, curved back, narrow-lanceolate, the upper ones gradually more ovate-lanceolate, quite entire, blunt with a purple tip, even on both sides, slenderly nerved, flat, a little fleshy, shrivelling: the flower has no scent, but is said by Catesby, to be variously shaded with red, orange, and lemon colours: it is remarked by Mr. Curtis, that it varies considerably in the breadth of its petals, in their colour and spots; and that it flowers usually in July or August.

The third has a subovate bulb in its native state, consisting of thick white loosely imbricate scales, putting out a few thick fibres from the bottom: the stem upright, a foot and half high, striated-angular, smooth or slightly hairy, with numerous scattered leaves, the upper ones spread-

ing out horizontally, acute, quite entire, absolutely hirsute, a little rough to the touch, dark green, slightly nerved, sessile, lanceolate-linear, three or four inches long; each, excepting the lower, frequently producing a roundish and shining pale-green bulb or two in the axil: the peduncle terminating, round, thick, somewhat villose; either solitary, or two, three or four together, forming a sort of umbel; some naked, others having a bracte or two: the flower without scent, red-orange within, pale-orange on the outside. It is a native of Austria, &c.

There are varieties with double flowers, with variegated leaves, with smaller stems, and the bulb-bearing fiery Lily, which seldom rises more than half the height of the others: the leaves are narrower: the flowers smaller, and of a brighter flame-colour, few in number and more erect; they come out a month before those of the common sort, and the stalks put out bulbs at most of the axils, which, if taken off when the stalks decay, and planted, produce plants.

The sub-varieties are: the great broad-leaved, the many-flowered, the small, and the hoary bulb-bearing Lily.

The fourth species rises with a strong stalk from three to four feet high: the leaves are broad; the flowers dark purple, with some spots of black; they are produced in loose spikes, appear in June, and have a disagreeable odour when near, but not so offensive as the seventh sort: the bulb is, according to Martyn, composed of lanceolate, yellow, loose scales, with thick, long, whitish fibres at bottom: the stem straight, round, shining, from a foot and a half to four feet in height, at the top of the bulb furnished with rooting fibres in whorls, pale green at bottom, the rest having black spots scattered over it, above and below the leaves are scattered, but in the middle they are in whorls; lanceolate, acute, somewhat nerved, quite entire, subpetioled; the stem terminates in a loose raceme, many-flowered, few-flowered, or sometimes one-flowered only: the peduncles purple, dotted with black, with lanceolate sharp bractes, two to the lower, and one to the upper flowers: the petals purple or pale, more or less spotted with black on both sides, the three outer hirsute, with a raised line along the middle. It is a native of the south of Europe, &c.

It varies with white flowers, with double flowers, with red flowers and hairy stalks, and with imperial divided stalks.

The fifth species has a pretty large yellow scaly root, from which arises an upright stalk nearly three feet high, with long narrow leaves, almost triangular, having a longitudinal ridge on their under side; they are deep green, and ter-

minate in acute points; the upper part of the stalk divides into four or five peduncles, each sustaining a single flower of a fine carmine colour, with a few dark spots scattered over it; they appear in July, and, when the season is not hot, continue a considerable time in beauty. It is a native of the Pyrenees, &c.

It varies with double red flowers, with white flowers, with double white flowers, with red spotted flowers, with white spotted flowers, with yellow flowers, with yellow spotted flowers, with early scarlet flowers, and the Major Scarlet Pompony.

The sixth species is from three to four feet in height; the leaves are much broader than those of the fifth sort, and appear as if they were edged with white; they are placed very closely upon the stalks: the flowers are of a bright scarlet, and seldom more than five or six in number: it flowers late in July, and in cool seasons continues in beauty great part of August. It is remarked by Linnæus, that the raceme, before the flowers open, is scarcely curved in, as in the fifth sort, and that the stem is clothed with clustered leaves to the very top. It is a native of the Levant.

According to Mr. Curtis, it varies in the number of flowers, from one to six, and the colour in some is of a blood red: also with deep scarlet flowers, with purple flowers, and with large bunches of flowers.

The seventh has a round stem, very smooth and even, panicled at top, two feet high and more; the branches alternate, divaricating, upright, like the stem, reflex at top, flower-bearing: the stem-leaves alternate, subpetioled, folded together at the base, ovate-oblong, acute, quite entire, smooth, five-nerved beneath, spreading; one flower at the end of each branch: the corollas are large and handsome: the petals oblong, acute, white with large purple spots and smaller black ones from the middle to the base: nectareous keel bearded: according to Catesby the flowers grow alternately on long footstalks, and are of an orange and lemon colour, thick spotted with dark brown; but Miller says they are produced in form of a pyramid, and when the roots are strong there are forty or fifty on a stalk, large, yellow with dark spots, and make a fine appearance, but smell so disagreeably, that few persons can endure to be near them: they appear at the end of June. It is a native of North America.

The eighth species has oblong and large bulbs: the stems from four to five feet high: the leaves oblong and pointed: the flowers large, yellow spotted with black, shaped like those of the orange lily, and the petals not turned back so much as in the other Martagons: they come out

in the beginning of August, and, when the roots are large, in great numbers, making a fine appearance. According to Catesby, on the top of the stem are about twelve pendulous flowers on long arched peduncles, and the petals are reflected very little. It flowers in July and August, and is found in North America.

There is a variety with larger deeper-coloured flowers.

The ninth has a roundish small bulb: the stem quite simple round, even, a foot high: the leaves lanceolate or lanceolate-linear, sessile, four or six, striated, rather blunt, even, upright; two or three of the upper ones usually alternate, narrower: the flowers terminating, few, an inch and a half in diameter, on very short, naked, almost upright peduncles: the petals ovate, blunt, even, striated, purple, not rolled back, attenuated at the base: the filaments shorter by half than the corolla: the anthers upright: the germ triangular and oblong: style none: stigmas three, oblong, curved back, almost the length of the germ. It is a native of Kamtschatka.

The tenth species has a smaller root than in the other sorts, scaly and white: the stem single, upright, near a foot and half high: the leaves in four or five whorls, short, pretty broad, obtuse: the stem terminated by two flowers which stand erect, upon short separate peduncles; they are shaped like those of the bulb-bearing fiery Lily, but the petals are narrower at their base, so that there is a considerable space between them, but upwards they enlarge and approximate, forming a sort of open bell-shaped corolla, but they terminate in acute points: are of a bright purple colour, marked with several dark purple spots towards the base. It flowers in July, and the seeds ripen at the end of September. It is a native of North America.

Culture.—All the sorts are capable of being increased by planting the off-sets of the root, and by sowing seeds to obtain new varieties.

All the sorts of these roots afford plenty of off-sets every year, which when greatly wanted may be taken off annually in autumn; but once in two or three years is better, according as they are wanted; the proper time for which is in summer and autumn, when the flower is past and the stalks decayed, either separating the off-sets from the mother bulbs in the ground, or taking the whole up, and separating all the off-sets, small and great, from the main bulbs; the small off-sets being then planted in beds a foot asunder and three inches deep, to remain a year or two; and the large bulbs again in the borders, &c. singly. The off-sets in the nursery beds may also, after having obtained size and

strength for flowering in perfection, be planted out where they are wanted.

The sowing of the seed is chiefly practised for the Martagons to obtain new varieties, which should be done in autumn, soon after the seed is ripe, in pots or boxes of rich light sandy earth, with holes in the bottoms half an inch deep; placing the pots in a sunny sheltered situation all winter, refreshing them at first often with water, and the plants will appear in the spring; when, about April, remove them to have only the morning sun all the summer, giving moderate waterings: in August the bulbs should be transplanted into nursery-beds in flat drills, an inch deep, and three or four asunder; when, as the bulbs will be very small, scatter the earth and bulbs together into the drills, covering them with earth to the above depth; and after having grown in this situation till the August or September following, they should be transplanted into another bed, placing them eight or nine inches each way asunder, to remain to show their first flowers; after which they may be finally planted out into the pleasure-ground.

New varieties of the other sorts may be raised in the same way.

The bulb-bearing varieties may also be increased by the little bulbs put forth from the axils of the leaves without taking up the old bulbs.

The same method of planting and general culture answers for all the different sorts.

The most proper time, as has been seen, for planting and transplanting them is in autumn, when their flowers and stalks decay, which is generally about September, the roots being then at rest for a short space of time, as well as for procuring roots to plant. The bulbs taken up at the above season may be kept out of ground, if necessary, till October or November: the White Lilies, however, do not succeed if kept long out of the earth, and all the others succeed best when planted again as soon as possible. The bulbs of all the sorts are sold at the nurseries.

They should be planted singly, as they soon increase by off-sets into large bunches, disposing them in assemblage in different parts of the borders, and towards the fronts of the principal shrubbery clumps; placing them three or four inches deep, and at good distances from one another, intermixing the different sorts, placing some forward, and others more backward, to effect the greater show and variety.

Some may likewise be planted in separate beds by themselves, twelve or fifteen inches asunder; either of different sorts together, or each in distinct beds, or in separate rows, &c.

After being thus planted out, few of the sorts require any particular culture, as they are capable of enduring all weather at every season. It is however necessary to destroy all weeds; and, as some of them run up with pretty tall slender stalks, to support them with sticks to preserve effectually their upright position, by which their flowers will appear to the best advantage.

Some of the more tender sorts, as the second, fourth, eighth, and tenth species, should, however, be protected in severe winters, by applying tanner's bark or some other similar substance over their roots.

They should all, as has been said, remain undisturbed two or three years, or longer, as by remaining they flower stronger after the first year; and having increased by off-sets into large bunches, many stalks will rise from each bunch of roots, so as to exhibit a large cluster of flowers: it is, however, proper to take up the bulbs entirely every three or four years at least, at the decay of the stalk, to separate the increased off-sets, both for propagation and to disburthen the main roots, and give them room to take their proper growth in.

After being taken up in the autumn, all the sorts should, as just observed, be replanted as soon as possible, especially the White Lily sorts, as they soon begin to emit roots.

They are all valuable as plants of ornament for the beauty of their flowers, which have a noble appearance: they are of course proper ornaments for the pleasure-ground; and when the different sorts are properly intermixed, they effect a most elegant variety, succeeding each other in blow upwards of three months. When wanted particularly for shady or close places, the common White Lily, Orange Lily, and common Martagons, are the most proper, as they thrive under trees. The Orange Lily also answers well in small gardens, in the midst of buildings in towns and cities. Besides planting the different sorts for the beauty of their flowers, many of the striped-leaved White Lily sorts should be placed towards the fronts of the most conspicuous parts for the beauty of their leaves in autumn, winter, and spring, which, if disposed alternately with the Common White Lily, whose leaves are entirely green, a most striking variety will be produced.

The tall-growing sorts are only proper for large borders and clumps, in mixture with other large herbaceous plants.

LILIACEOUS PLANTS, such as resemble those of the Lily kind, in their flowers having six regular petals, in the form of a Lily, or three, or even one petal deeply divided into six segments, assuming a lily-flower form; they have not,

however, all flowers so large as that of the Lily, some being considerably smaller; and as the common Lily has no calyx, so several of the liliaceous flowers are also destitute of a cup; and others have cups, which are principally of that sort called a spathe. They may therefore be distinguished into such as have cups and such as have not.

Those without cups are: all the different sorts of common lily; the tulip, all the kinds; fritillary, and crown imperial; hyacinth; star of Bethlehem; bastard star of Bethlehem; tuberose; asphodel; squill; hemerocallis, or day-lily; anthericum, or spider-wort; aloe; yucca, or Adam's needle; gloriosa, or superb lily, &c.

Those with spathes or cups are: the crocus; galanthus, or common snow-drop; leucojum, or great snow-drop; daffodil, narcissus, and jonquil; crinum, or asphodel lily; colchicum; iris, or flower-de-luce; hæmanthus, or blood-flower; gladiolus, or sword-lily; Virginia spider-wort; amaryllis, including the Guernsey lily, belladonna lily, and Jacobæa lily, &c.; paneratum lily, &c.

The greater part of these liliaceous plants of both kinds are bulbous-rooted; some, however, have tuberous and some fibrous roots; and all of them are perennial in root, but annual in stalk.

They are all ornamental garden-flowers, and most of them sufficiently hardy to grow in the open ground; though a few are proper for the green-house and stove. See the different *Genera*.

LILY. See **AMARYLLIS**, and **LILIUM**.

LILY-OF-THE-VALLEY. See **CONVALLARIA**.

LIME TREE. See **CITRUS**.

LIME WATER, such as is prepared by slaking caustic lime in soft water, in the proportion of half a peck of the former to thirty-two gallons of the latter, letting them remain some time before they are made use of, stirring them well, two or three times a day, for two or three days. This liquid, when the lime has subsided, is found highly useful in clearing fruit-trees from the ravages of the Aphis Puceron, or Vine-Fetter. It should be applied once a day by means of an engine so as to be thrown as much as possible on the under sides of the leaves, and with considerable force, pressing the fore finger upon the end of the pipe, to make it spread like small rain, and taking care that every part of the tree be well watered. It should be done as much as possible in cloudy weather, and when the sun is off the walls. Where the trees have an easterly aspect, they may be watered about half past eleven o'clock

in the forenoon, and in a northern one, the first thing in the morning; but in a southern aspect, about four o'clock in the afternoon. And when northerly or easterly winds and frosty nights prevail, it should be discontinued till the weather becomes mild. The trees should always get dry before night, and never be watered when the sun is upon them. Care must likewise be taken that the grounds of the lime be not made use of, as it would make the trees have a disagreeable appearance. See PUCERON and VINE-FRETTER.

LIMODORUM, a genus containing plants of the bulbo-tuberous-rooted herbaceous perennial kind.

It belongs to the class and order *Gynandria Diandria*, and ranks in the natural order of *Orchideæ*.

The characters are: that the calyx has vague spathes: spadix simple: there is no perianthium: the corolla, petals five, ovate-oblong, about equal, spreading: the superior ones converging: nectary one-leaved, concave, footstalked, within the lowest petal; the length of the petals: the stamina two: filament an oblong, ascending body, the length of the corolla: anthers two, ovate, looking forwards: the pistillum is a columnar germ, the length of the corolla; inferior: style filiform, growing to the body of the filaments: stigma funnel-form: the pericarpium is a columnar capsule three-valved, one-celled, gaping at the corners: the seeds numerous, saw-dust-like.

The species cultivated are: 1. *L. tuberosum*, Tuberous-rooted Limodorum: 2. *L. altum*, Tall Limodorum: 3. *L. Tankervilleæ*, Chinese Limodorum.

The first has a tuberous root: the stem a foot and half high: the number of flowers not exceeding five, dark purple: in a more luxuriant state it is probably a larger plant, and produces more flowers. It is a native of North America.

The second species has a root shaped like that of the true Saffron, but the outer cover of a darker brown colour; from this come out two or three leaves nine or ten inches long, and near three quarters of an inch broad in the middle, being contracted towards both ends, terminating with long acute points, folding over each other at their base; they have five longitudinal furrows, like the first leaves of young palms: the flower-stalk arises immediately from the root, on one side of the leaves; it is naked, smooth, and of a purplish colour towards the top: it is near a foot and a half high, and terminated by a loose spike of purplish red flowers on short peduncles. The bulb tubercled, roundish, of a fleshy and fibrous

substance, covered with a coriaceous shining skin, and having some tomentose white fibres underneath: the leaves from the bulb, vernal, two feet long, broad-lanceolate, longitudinally folded at the nerves, even, very like those of a young plant of the coco palm: scape simple, upright, sometimes subdivided at top, two feet high, even, round; it has little sheaths on it, which are remote, præmorse, embracing, netted, pale: the flowers terminating, scattered, alternate, large, purple, sometimes varying to white. It is a native of the West Indies, flowering in June and July.

The third has a bulb fibrous root, from which proceed three or four oblong, oval, pointed leaves plaited and narrowed at the base, about a foot and a half in length, and seven inches in breadth in the middle part: the flower-stalk rises from the root upwards of two feet in height, and is furnished with a long spike of large beautiful flowers, each consisting of five oblong spreading petals of a pure white on their upper-side, and brown underneath, with a large concave nectarium tinged with red towards the extremity, and succeeded by a three-cornered columnar germen inclosing the seeds. It is a native of China, flowering in March and April.

Culture.—These plants are increased by planting the off-sets from the roots in pots of bog earth, plunging them in the first sort in a mild tan-pit, and in the others in the tan hot-bed of the stove. The proper time of taking them off is when the plants are the most destitute of leaves.

The two last sorts should have a loamy mould, and but little water in the winter season.

The first requires the protection of a good green-house in winter, and the two last must be kept in the bark-bed of the stove.

They afford variety in the green-house and stove collections.

LIMON. See CITRUS.

LINING HOT-BEDS, the practice of applying a layer of hot-dung to the sides of the beds to revive and keep up the declining heat. It is essentially necessary in the culture of plants on dung hot-beds in early seasons in winter or spring, until May. As these hot-beds generally in from three or four to five or six weeks, according to their substance, begin to decline in their degree of heat, they require a revival to continue them in regular heat; which in dung hot-beds can only be effected in this manner. It is applied to one or both sides as there may be occasion.

Thus, by the occasional repetition of two, three, or more linings, a hot-bed is continued in a proper degree of heat several months, as exem-

plified in early cucumber and melon hot-beds, which, without the aid of occasional linings, would not retain sufficient heat to forward their respective plants, &c. to proper perfection.

Dung for this purpose must be of the best fresh horse stable kind, moist and full of a steamy lively heat, being prepared in the manner described under *HOT-BED*, and in proper quantity to make the lining substantial, fifteen or eighteen inches wide, and as high as the dung of the hot-bed; as when too slender they do not effect the intended purpose, especially in early beds, or when the heat is considerably decreased.

In early hot-bed work, care should be taken, according to the extent of the bed or beds and season of the year, to allot and reserve a sufficiency of dung for linings: early beds in very cold weather will generally require more substantial and frequent linings than later-made beds in the advanced spring months; and some hot-beds, for slight or temporary uses, just to raise plants for two or three weeks, will sometimes require but very little or no linings. Hot-beds made late, as in the beginning or any time in May, will need but very trifling linings, or some not at all, except in particular uses as when plants are rather backward in growth, the weather cold, and the bed declined much in heat, when, probably, even in May, or beginning of June, a final moderate lining may be necessary.

The requisite linings should be applied to the respective hot-beds in proper time, as it may be necessary on examining the state of heat, not letting them decline too considerably before they are applied, but to continue always a moderately lively heat, but never violent: linings are sometimes applied by degrees, raising them only half way at first, adding more in height in a few days, and thus proceeding till they are raised to the height of the hot-beds.

In the application of linings, it is generally necessary to line only one side at a time, commonly the back part of the bed first; and in a week or fortnight after to line the front side, and both ends if necessary; or in particular cases of the hot-bed having suddenly declined, or been permitted to decrease very considerably in heat before applying the lining, to line both sides moderately at once, about twelve or fifteen inches in width, but only as high as the dung of the bed at first; being afterwards a little augmented by degrees according as the dung of the lining settles.

The general requisite substance of the linings is from twelve to fifteen or eighteen inches width in dung, and as high as the dung of the

bed, or sometimes a few inches higher: but for early bed of cucumbers, melons, or other plants of long continuance in hot-beds, they should generally be laid from fifteen to eighteen inches in width at bottom, as conceived necessary, narrowing the width gradually upwards to eight, ten, or twelve inches at top, which may be raised at once to the full height of the dung of the bed, or a few inches higher up the side of the frame, to allow for settling; but with a strong lining, be cautious in raising it much above the dung of the hot-bed, especially when made of very strong, hot, steamy dung, for fear either of its throwing in a too strong heat above to burn the internal earth of the bed, or imparting a copious rank steam to penetrate within the frame, which would steam-scald tender plants.

In general, as soon as the linings are raised to the intended height, it is proper to lay a stratum of earth at top two inches thick, close up to the bed or bottom part of the frame, sloping a little outward to throw off the falling wet of rain, snow, &c. which top covering of earth is essential, both to keep the heat of the linings from escaping too considerably above, in order that it may be directed more effectually to its intended purpose of imparting its whole or principal heat internally to the revival of that of the bed, and prevent the strong steam arising immediately from the rank dung from entering the frame at bottom, or through any small crevice, or at top, when the lights are occasionally raised for the admission of fresh air, as the rancid dung steam thus produced, without being moderated by first passing through a stratum of earth, if it should enter within the frame considerably, would prove very pernicious to most plants, and the total destruction of some kinds.

As the heat of the linings declines to any extent, they must be renewed by a supply of fresh hot dung. This may sometimes be effected by turning over, and shaking up the same dung mixedly together, directly forming it again into a lining: or some of the best or least decayed or exhausted parts of the old lining may only be used, mixing it up properly with a good supply of new dung, applying it immediately in a proper substantial lining as before.

When the dung of the linings is greatly exhausted, fresh dung should mostly be used in the renewal.

Linings of hot dung are sometimes used substantially, in working some sorts of forcing-frames, in raising early flowers and fruits, by applying the dung against the back of the frame, two or three feet in width at bottom, narrowing gradually to a foot and a half, or less, at

the top, raising the whole according to the height of the frame, from four or five to six or seven feet; which heating considerably against the whole back of the frame, communicates the heat internally, by which the different plants are forwarded to early production; supporting the internal heat by renewing the linings. See FORCING FRAME.

Linings of dung are also sometimes used in supporting the heat of nursery hot-beds for young pine-apple plants, and some other exotics of the hot-house or stove, both in dung and tan-bark hot-beds, under proper frames and glasses; as well as those wintered in these detached hot-beds distinct from the hot-house, &c. and in which a constant regular heat, almost equal to that of the stove, must be supported, so that, when the natural heat of the bed is on the decline, a strong lining of hot dung must be applied, half a yard or two feet wide below, narrowing moderately upward, and continued on both sides occasionally; and as the heat of these linings subsides, it must be immediately renewed by a supply of fresh dung, either worked up with the best of that of the declined lining, or, if this is much decayed, wholly of new; and thus the hot-beds maintained in a proper degree of heat from autumn till spring.

The decayed dung of the different linings, when done with, becomes excellent manure for the kitchen-garden.

LINUM, a genus containing plants of the herbaceous, annual, and perennial shrubby kinds.

It belongs to the class and order *Pentandria Pentagynia*, and ranks in the natural order of *Grinales*.

The characters are: that the calyx is a five-leaved lanceolate perianthium, upright, small, permanent: the corolla funnel-form: petals five, oblong, gradually wider above, obtuse, more spreading, large: the stamina have five awl-shaped filaments, upright, length of the calyx (also five rudiments, alternating): anthers simple, arrowed: the pistillum is an ovate germ: styles five, filiform, upright, length of the stamens: stigmas simple, reflex: the pericarpium a globose capsule, rudely pentagonal, ten-valved, gaping at the tip: partitioned membranaceous, very thin, connecting the valves: the seeds solitary, ovate-flatish, acuminate, smooth.

The species are: 1. *L. usitatissimum*, Common Flax; 2. *L. perenne*, Perennial Flax; 3. *L. suffruticosum*, Shrubby Flax; 4. *L. arborescens*, Tree Flax; 5. *L. Africanum*, African Flax.

The first has an annual, simple, fibrous, pale

VOL. II.

brown root: the stem upright, eighteen inches, two feet, and even more in height, round, smooth, leafy, branched only at top: the leaves are sessile, growing close together, almost upright, perfectly entire: the flowers large, growing in a panicle, on round smooth peduncles: the calycine leaflets ovate-keeled, with a membranous edge, when magnified appearing to be fringed with hairs: the petals wedge-shaped, deciduous, sky-blue, streaked with deeper-coloured lines; white at the claws, and somewhat gnawed at the tip. It is a native of Egypt, flowering in Jude and July.

It may be said to be one of the most valuable plants in the whole vegetable kingdom; as from the bark of its stalks is manufactured flax or lint, for making all sorts of linen cloth; from the cloth, when worn to rags, is made paper: and from the seeds of the plant linseed oil is expressed, which is much used by painters, and in other arts; and the refuse, after expression, forms the oil-cakes so valuable in the fattening of cattle and sheep.

In the second species, from its perennial root rise three or four inclining stalks, having short narrow leaves towards their base, but scarcely any about the top: the flowers are produced at the ends of the stalks, sitting very close; they are blue, and about the size of the cultivated sort, being succeeded by pretty large round seed-vessels, ending in acute points. Its flowers appear from June to August, and are of a delicate texture and very elegant blue colour, and the roots continue four or five years.

There is a variety which is procumbent, with smaller flowers.

The third has a shrubby stalk a foot high, sending out several branches: the leaves very narrow, coming out in clusters, but on the flowering branches broader and longer: the flowers at the ends of the branches, erect, on long slender peduncles: the calyxes acute-pointed: the petals large, entire, white, but before the flowers open pale yellow: they appear in July, but the seeds seldom ripen in this climate: the flowering stalks decay in the autumn, but the lower shrubby part continues with the other branches all the year. It is a native of Spain, &c.

The fourth species forms, if not a tree, as its name implies, a shrub of the height of several feet: it begins to flower in March, and continues flowering to the close of summer; but has not yet produced seeds in this climate. It is a native of the island of Candia.

The fifth has a suffruticose stiff stem, a foot high, round, with simple branches: the leaves are sessile, upright, even, generally shorter than

K

the internodes; the flowers in a terminating umbel, which is four- or five-cleft, with dichotomous rays: the petals are yellow with villose claws, and turning tawny: the calyx acuminate and rugged at the edge. It is a native of Africa, flowering in June and July.

Culture.—These plants may be increased by seeds and layers, or cuttings.

The two first sorts are raised by sowing the seeds in the early spring months, as March or the following month, the former in fields or plantation-grounds, where the soil is fresh, good, and well reduced into order by frequent digging over, or ploughing and harrowing, in narrow drills, or broadcast, and raked or harrowed in with a light harrow: the plants being afterwards kept perfectly clean from weeds by repeated hoeings.

Towards the end of August, when the plants have attained their full growth, and begin to turn yellow at bottom, and brown at top, and their seeds to ripen, it is proper time to pull them; though, if it were not for the sake of the seed, they might be pulled a little before the seeds ripen, by which the flax is generally better coloured and finer; but if suffered to stand till the seeds are fully ripe, it is commonly stronger, somewhat coarser, and more in quantity. It should be pulled up by handfuls, roots and all, shaking off all the mould; then either spreading them on the ground by handfuls, or binding them in small bunches, and setting them upright against one another, for ten days or a fortnight, till they are perfectly dry, and the seed fully hardened, then housed, and the seed thrashed out, cleaned, and placed in a dry airy situation, being afterwards put up for use. The flax, after being rippled and sorted, should be carried to a pond of nearly stagnant water, being placed in it with the bundles crossing each other in different directions, so as to keep the whole in a close compact state, being kept just below the surface of the water, by proper weights applied upon it. It should remain in this steep till the stems become brittle and the bark readily separates, when it must be taken out and spread thinly on a short pasture, being occasionally turned until it becomes perfectly bleached and dry, when it is in a proper state for the purpose of being converted into flax.

The latter, or perennial sort, should be sown in a bed or border of good earth, in shallow drills at the distance of six inches; and when the plants are two or three inches in height they should be thinned to the same distances, and in autumn be planted out in the places where they are to grow. But it is probably a better practice to sow them at once in the places

where they are to grow, thinning them out properly afterwards.

The three other sorts may be best increased by planting cuttings of the branches in pots of light fresh earth, plunging them in the tan hot-bed, or by layers laid down in the later summer months. When the plants in either mode have stricken good root, they may be removed into separate pots, and be managed as other tender exotic plants that require the protection of the green-house.

They may likewise be raised from seeds when they can be procured, which should be sown in pots and placed in a hot-bed in the spring season.

A few plants of the two first sorts may be introduced in the clumps and borders of the pleasure-ground; and the three other sorts afford variety in green-house collections among other potted plants.

LION'S FOOT. See CATANANCHE.

LION'S TAIL. See PHLOMIS.

LIQUIDAMBAR, a genus furnishing plants of the hardy deciduous tree kind.

It belongs to the class and order *Monoclea Polyandria*, and ranks in the natural order of *Coniferae*.

The characters are: that the male flowers are numerous, on a long, conical, loose ament: the calyx a common four-leaved involucre; leaflets ovate, concave, caducous; the alternate ones shorter: there is no corolla: the stamina have numerous filaments, very short, on a body convex on one side, flat on the other: anthers upright, twin, four-furrowed, two-celled: the female flowers at the base of the male spike, heaped into a globe: the calyx an involucre as in the male, but double: perianthium proper bell-shaped, cornered, several, connate, warty: there is no corolla: the pistillum is an oblong germ growing to the perianthium: styles two, awl-shaped: stigmas growing on one side, length of the style, recurved, pubescent: the pericarpium has as many capsules, ovate, one-celled, bivalve at the tip, acute, disposed into a globe, woody: the seeds several, oblong, glossy, with a membrane at the point mixed with a great many chaffy corpuscles.

The species are: 1. *L. styraciflua*, Maple-leaved Liquidambar, or Sweet Gum: 2. *L. imberbe*, Oriental Liquidambar.

In the first, in its native situation, the trunk is commonly two feet in diameter, straight, and free from branches to the height of about fifteen feet; from which the branches spread and rise in a conic form to the height of forty feet and upwards from the ground: the leaves are five-pointed, divided into so many deep sections, (as

sometimes seven,) and set on long slender petioles: they are shaped somewhat like those of the lesser Maple, but of a dark green colour, with their upper surfaces shining: a sweet glutinous substance exudes through their pores in warm weather, which renders them clammy to the touch. In February, before the leaves are formed, the blossoms begin to break forth from the tops of the branches into spikes of yellowish-red, pappose, globular flowers, which swell gradually, retaining their round form, to the full maturity of their seed-vessels, which are thick set with pointed hollow protuberances, and, splitting open, discharge their seeds. It is a native of North America.

In the second species the leaves have their lobes shorter, and much more sinuated on their borders, ending in blunt points, and not serrated. They have also none of those tufts of hair which are found on the leaves of the first sort: its native country is unknown.

Culture.—These plants are increased by seed, and layers.

The seed should be sown as soon as it is procured from abroad, in spring, in a bed of light earth, half an inch deep, when the plants will rise some the same year and others not till the spring following, moderate waterings being occasionally given, keeping them clean from weeds all summer, and protecting them from severe frost the first two winters. When two years old, plant them out in spring, in nursery rows, two feet asunder, to remain three or four years, or till wanted for planting out in the shrubbery, or other places.

Some sow the seeds in pots, or boxes, in order to move them to different situations as the season requires; and that when the plants do not come up the same year, the pots may be plunged in a hot-bed in the following spring to forward their rising.

The layers should be made from the young shoots of the preceding summer, by slit-laying, when most of them will be rooted by the following autumn, though in a dry poor soil they are sometimes two years before they are sufficiently rooted for being removed to plant out.

These trees have great merit for ornamenting shrubbery plantations, in assemblage with others of similar growths, being handsome, straight-growing trees, with fine heads, as well as adapted for planting, detached as single objects, in spacious short grass openings, in which they appear very ornamental, perfuming the air all round in summer.

They succeed in any common soil and situation, and endure the severest cold without injury. They are usually kept in the nurseries for sale.

LIQUORICE. See GLYCYRRHIZA.

LIRIODENDRUM, a genus containing a plant of the hardy deciduous ornamental tree kind.

It belongs to the class and order *Polyandria Polygynia*, and ranks in the natural order of *Coadunatæ*.

The characters are: that the calyx is a proper two-leaved involucre: the leaflets triangular, flat, deciduous: perianthium three-leaved: leaflets oblong, concave, spreading, petal-form, deciduous: the corolla six-petalled, bell-shaped: petals spatulate, obtuse, channelled at the base; the three exterior deciduous: the stamina have numerous filaments, shorter than the corolla, linear, inserted into the receptacle of the fructification: anthers linear, growing longitudinally to the sides of the filament: the pistillum has numerous germs, disposed into a cone: style none: stigma to each globose: there is no pericarpium: seeds imbricated into a body resembling a strobile: the seeds numerous, ending in a lanceolate scale, emitting an acute angle towards the base of the scale from the inner side, compressed at the base, acute.

The species cultivated is: *L. tulipifera*, Common Tulip-Tree.

It has the young shoots covered with a smooth purplish bark; they are garnished with large leaves, whose foot-stalks are four inches long; they are ranged alternate; the leaves are of a singular form, being divided into three lobes; the middle lobe is blunt and hollowed at the point, appearing as if it had been cut with scissors: the two side lobes are rounded, and end in blunt points: the leaves are from four to five inches broad near their base, and about four inches long from the foot-stalk to the point, having a strong midrib, which is formed by the prolongation of the foot-stalk: from the midrib run many transverse veins to the borders, which ramify into several smaller: the upper surface of the leaves is smooth, and of a lucid green, the under is of a pale green: the flowers are produced at the end of the branches; they are composed of six petals, three without, and three within, which form a sort of bell-shaped flower, whence the name: these petals are marked with green, yellow, and red spots, making a fine appearance when the trees are well charged with flowers: the time of flowering is in July; and when the flowers drop, the germ swells, and forms a kind of cone, which does not ripen in this climate. It is a native of North America.

It grows so large as to be a tree of the first magnitude in its native situation, and is generally known by the title of poplar: of late

here have been great numbers raised from seeds here, so that they are become common in the nurseries; and there are many of the trees in different parts which annually produce flowers.

Culture.—This plant may be increased by sowing the seeds, imported annually from America by the seed-dealers, in spring, either in the full ground, in beds of rich light earth, in a warm situation, placing the seed length-wise, and covering it nearly an inch deep, or in pots or boxes, plunging them in a gentle hot-bed: when the young plants appear they should be well screened from the sun, and have free air. They usually come up the same season; when in the former method water should be given them in dry weather; and if the bed be arched over with hoops, to have occasional shade from the mid-day sun in scorching weather, it will be beneficial to the germination of the seeds and growth of the young plants; continuing the waterings with care occasionally during the summer; and in winter, sheltering them with mats in frosty weather to preserve their tops, which are sometimes a little tender the first year, and apt to suffer.

When the plants are two years old, they should be set out in spring in nursery-rows, two feet distant, and a foot asunder in the rows; to remain a few years, till from three to six or eight feet high, when they may be planted where they are to remain.

They are raised best in the open ground, where the beds are prepared of good mellow rich earth, blended with old rotten cow-dung, sifting over the seeds fine turf-mould, mixed with fine sea or pit-sand.

These trees succeed best afterwards in a light soil, not too dry. They should have their roots and branches as little pruned as possible.

They are highly ornamental in large plantations, among others of similar growth, and have a fine effect when planted out singly in large openings, kept in short grass, in pleasure-grounds.

LOBELIA, a genus containing plants of the herbaceous and under shrubby perennial kind.

It belongs to the class and order *Syngenesia Monogamia*, and ranks in the natural order of *Campanaceæ*.

The characters are: that the calyx is a one-leaved perianthium, five-cleft, very small: growing round the germ, withering: toothlets nearly equal: the two superior ones looking more upward: the corolla one-petalled, irregular: tube cylindric, longer than the calyx, divided longitudinally above: border five-parted, divisions lanceolate; of which the two superior ones are smaller, less reflex, more deeply divided, constituting an upper lip: the three inferior ones

more spreading, frequently larger: the stamina have five awl-shaped filaments, the length of the tube of the petal, connate above: anthers connate into an oblong cylinder, gaping five ways at the base: the pistillum is a sharp-pointed, inferior germ: style cylindric, length of the stamens: stigma obtuse, hispid: the pericarpium an ovate capsule, two- or three-celled, two- or three-valved, gaping at the top, girt by the calyx: dissepiments contrary to the valves: the seeds a great many, very small: receptacle conic.

The species cultivated are: 1. *L. cardinalis*, Scarlet Lobelia, or Cardinal's Flower; 2. *L. siphilitica*, Blue Lobelia, or Cardinal Flower; 3. *L. longiflora*, Long-flowered Lobelia; 4. *L. pinifolia*, Pine-leaved Lobelia; 5. *L. inflata*, Bladder-podded Lobelia.

In the first, the root is composed of many white fleshy fibres: the lower leaves are oblong, and of a dark purplish colour on their upper side: the stalks are erect, about a foot and half high, with leaves about three inches long, and an inch and half broad in the middle, on very short petioles and placed alternately: the stalk is terminated by a spike (raceme) of flowers, of an exceeding beautiful scarlet colour; they have a pretty long tube, which is a little incurved, and at the top they are cut longitudinally into five segments; the two upper, which are the smallest, are greatly reflexed; the three under, which form the lower lip, are longer, and spread open. They appear at the end of July and in August, when they make a fine appearance for a month or more, and when the autumn proves favourable produce good seeds. It grows naturally in North America.

The second species has a perennial root: the stem simple, from a foot to two feet in height, and upwards, strong, simple, smooth, with angles formed by the decurrent edges of the leaves having stiffish hairs on them: the leaves are alternate, sessile, somewhat rugged: the flowers axillary, solitary, numerous, large, on short peduncles, forming altogether a long spike of a pale blue colour. It is a native of Virginia, flowering from August to October.

The third is an annual herbaceous elegant plant, seldom above fourteen or sixteen inches in height; the whole of it rough-haired: the stem almost upright, very much branched from all the axils: the leaves are alternate, sessile, subpinnatifid-toothed, sharpish, smooth, half a foot long: the peduncles one-flowered, axillary, solitary, villose. The whole plant is poisonous. It is a native of Jamaica, flowering from June to August.

The fourth species is a shrubby, upright, branched plant, the branches surrounded with

Lobelia Cardinalis.
 1 Scarlet Lobelia or Cardinals flower.

Lilium Candidum.
 2 White Lily.

abundance of narrow sharp leaves an inch in length: the flowers many, small, blue, at the tops of the twigs, among the leaves. It is a native of the Cape of Good Hope.

The fifth is a biennial plant in this climate: the stems channelled, hairy, two feet high: the leaves about two inches long, and one broad in the middle, sessile, light green: flowers small, on long, slender, axillary peduncles, forming a loose spike: the corolla light blue. It flowers in July, and is a native of Virginia, &c.

Culture.—The two first kinds may be increased by seed, cuttings of their stalks, and parting the roots.

The seeds should be sown in autumn, or early in spring, in a warm border, or in pots or boxes, so as to be moved to different situations in different seasons, to have shelter from frost, and shade from the mid-day sun in summer. Those sown in autumn generally come up more freely the following spring than those which are sown in that season. They should have shelter in hard frosts, either under a frame, or awning of mats, but be fully exposed in mild weather, giving occasional waterings in the spring and summer. When the plants have attained two or three inches growth, they should be pricked out in separate small pots of rich earth, giving water, and placing them in the shade till fresh rooted, repeating the waterings occasionally in hot dry weather, and shifting them into larger pots as they may require; in winter moving them into a frame to have occasional shelter from inclement weather; and in the spring following some of them may be turned out into the full ground about March, when they will flower the ensuing summer. Some should also be retained in pots to be moved under shelter in winter, as a reserve in case those in the open air should be killed by frost.

As these plants generally flower in the greatest perfection the first and second year of their blowing, it is proper to raise a supply of new plants every year or two, in order to have them flower in the utmost perfection every year.

The cuttings of the young stalks should be divided into lengths of five or six inches, and be planted in an easterly border, two parts deep, being covered down with hand-glasses, and watered occasionally. They mostly emit roots, and form young plants in a month or six weeks; when the glasses should be taken away, and the plants managed as the others.

These hardy sorts sometimes afford off-sets from their sides at bottom, which may be separated in autumn, and potted for young plants, being managed as the seedlings.

The last three sorts may also be raised by seeds procured from abroad, which should be sown in

pots of light sandy earth in the autumn, and plunged in the bark-bed; and when the plants are three inches high, planted in separate pots, being replunged in the bark-bed, giving water and occasional shade till they are fresh rooted. They must remain constantly in the hot-house, and have frequent moderate waterings given them.

The first two sorts have a fine appearance in the borders and clumps of pleasure-grounds, where they will succeed when protected in winter from frosts.

And the tender sorts afford a fine variety in hot-house collections.

LOCUST-TREE. See CERATONIA.

LOGWOOD. See HÆMATOXYLUM.

LONDON-PRIDE. See SAXIFRAGA.

LONICERA, a genus containing plants of the deciduous flowering shrubby and evergreen kinds.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Aggregatæ*.

The characters are: that the calyx is a five-parted, superior perianthium, small: the corolla one-petalled, tubular: tube oblong, gibbous: border five-parted: divisions revolute, one of which is more deeply separated: the stamina have five awl-shaped filaments, nearly the length of the corolla: anthers oblong: the pistillum is a roundish, inferior germ: style filiform, the length of the corolla: stigma obtuse-headed: the pericarpium is an umbilicated, two-celled berry: the seeds roundish, and compressed.

The species are: 1. *L. nigra*, Black-berried Upright Honeysuckle; 2. *L. Tatarica*, Tartarian Upright Honeysuckle; 3. *L. Xylosteum*, Fly Honeysuckle; 4. *L. Pyrenaica*, Pyrenean Upright Honeysuckle; 5. *L. alpigena*, Red-berried Upright Honeysuckle; 6. *L. cærulea*, Blue-berried Upright Honeysuckle; 7. *L. symphoricarpos*, Shrubby St. Peter's-wort; 8. *L. diervilla*, Yellow-flowered Upright Honeysuckle; 9. *L. periclymenum*, Common Honeysuckle; 10. *L. caprifolium*, Italian Honeysuckle; 11. *L. sempervirens*, Trumpet Honeysuckle; 12. *L. grata*, Evergreen Honeysuckle.

The first is three or four feet in height: the leaves are small, the younger ones hirsute, quite entire, but plaited a little, so as to appear serrate: stipules ovate-lanceolate: bractes two dry scales and three transverse broad leaflets: the peduncles are axillary, slender, an inch long, opposite: the calyx broadish: the corolla purple on the outside, white within, or quite white, pubescent: the berries black, a little oblong, containing three, five, and sometimes ten seeds. It is a native of

France, &c. flowering in March, April, and May.

The second species grows about the same height with the first and sixth sorts, and bears a great resemblance to them in the branches; but the leaves are heart-shaped, and the berries are red, growing sometimes single, at others double, and frequently there are three joined together; they are about the same size with the first sort. It is a native of Russia, flowering in May and June.

It varies with white flowers in shady groves.

The third rises with a strong woody stalk, six or eight feet high, covered with a whitish bark, dividing into many branches: the leaves are ovate, opposite, entire, and covered with a short hairy down, soft, like cloth to the touch: the flowers come out on each side of the branches opposite, on slender peduncles, each sustaining two white flowers standing erect: the three lower segments of the corolla are narrow and reflex, the other two are broader and upright. It is a native of the North of Europe, flowering in May.

The fourth species seldom rises more than three or four feet high, dividing into several spreading irregular branches: the leaves are smooth: the flowers come out from the side of these on slender peduncles, each sustaining two white flowers, which are cut into five segments almost to the bottom. It is a native of the Pyrenean Mountains, flowering in April.

The fifth has a short thick woody stem, which divides into many strong woody branches growing erect: the leaves are petioled, entire, dark green above, but pale underneath: the flowers upon very long slender peduncles, which come out opposite on each side of the branches, at the base of the leaves; they are red on the outside, but pale within, shaped like those of the third sort, but a little larger, and standing erect. They appear at the end of April, and are commonly succeeded by two ovate red berries, joined at the base, and having two punctures. It is a native of the South of Europe.

The sixth species seldom rises more than four or five feet high: the branches are slender, covered with a smooth purplish bark: the joints are distant, where leaves come out opposite, and sometimes there are two on each side: the peduncles are very short, each sustaining two white flowers, succeeded by blue berries single and distinct. The flowers appear in May (March or April), and the berries ripen in August. It is a native of Switzerland.

The seventh is about four feet in height, sending out many slender branches: the leaves are ovate, hairy, opposite, on very short petioles:

the flowers are produced in whorls round the stalk; they are of an herbaceous colour, and appear in August: the fruit, which is hollow, and shaped like a pottage pot, ripens in the winter: the corollas are regular and bell-shaped: the fruit fleshy, globular, the form and size of the flowers of *Arbutus*, four-celled, containing cartilaginous roundish seeds. It is a native of Virginia, &c. flowering in August and September.

The eighth species is a low shrub, seldom rising more than three feet high: the stalks are slender and woody, and have a reddish-coloured bark: the leaves oblong, pointed, slightly serrate, opposite: the flowers small, pale yellow, two or three on each division of the raceme: the berries oval, black, four-celled, with one hard seed in each cell: the roots creep far under ground, and send out many stems: many of these which come up in the spring produce flowers the same year, so that there is generally a succession of them from May to September: the shoots of the former year flowering early, the side branches soon following, and then the young shoots. It is a native of North America.

The ninth trails over bushes, and twines round the boughs of trees, with its very slender hairy (or smooth) branches, which are opposite, and commonly stained with purple, in part at least, or on one side: the leaves opposite, ovate, smooth (or hairy), underneath glaucous, all distinct and more separated from the stem, though even in these there is a slight membranaceous ring running round the branch, and connecting the two opposite leaves: the upper floral leaves are sessile and cordate: the peduncles short, single, or more often triple, covered with glandular hairs, as are also the calyx, and tube of the corolla: the flowers are in a thick roundish whorled spike, many together (from ten or twelve to nineteen or twenty); the tube an inch long, curved a little; the border two-parted, both parts reflex; the upper one divided into four blunt and nearly equal segments, the lower one linear and entire: the tube is wider and shorter, the border much longer than in the tenth sort: the border being turned back, the stamens stand much above the corolla, and the pistil much above them: the corollas are usually red on the outside, and yellowish within, but they vary much in colour, between red, purple, and yellow, and in the shade are very pale: they smell very sweet, especially in the evening. It is a native of most parts of Europe, flowering here from the end of May to July.

The great beauty and exquisite fragrance of the flowers of this plant give it a place in most ornamental plantations. In climbing it turns from east to west, with most of our climbers; and in common with them it bears clipping and

pruning well; for, in a state of nature, those plants that cannot ascend without the assistance of others are often liable to lose large branches; they have therefore a proportional vigour of growth to restore accidental damages. It is subject, when placed near buildings, to be disfigured and injured by *Aphides*, vulgarly termed *Blights*; these insects are not very numerous in spring, but as the summer advances they increase in a surprising degree; their first attacks should of course be watched, and the branches they first appear on be cut off and destroyed, for when they have once gained ground they are defended by their numbers. Small plants may be cleared of them by tobacco dust or Spanish snuff, but this is not practicable for large trees: the leaves are likewise liable to be curled up by a small caterpillar, which produces a beautiful little moth, *Phalaena Tortrix*. In the evening some species of *Sphinxes* or Hawk-Moths are also frequently seen to hover over the blossoms, and with their long tongues to extract the honey from the very bottom of the flowers.

There are several varieties; as the Late Red, which produces a greater quantity of flowers together than either the Italian or Dutch sorts, making a finer appearance than either of them during the time of flowering; but it has not been so long cultivated as the latter.

It was formerly termed Flemish Honeysuckle. There are also sometimes varieties with striped leaves.

The Dutch variety may be trained with stems, and formed into heads, which the wild sort cannot, the branches being too weak and trailing for the purpose: the branches of this are smooth, of a purplish colour, garnished with oblong oval leaves, three inches long, and an inch and three quarters broad, of a lucid green on their upper side, but pale on their under, having very short foot-stalks; they are placed by pairs, but are not joined at their base: the flowers are produced in bunches at the end of the branches, each flower arising out of a scaly cover, which, after the flowers fade, forms an oval head, whose scales lie over each other like those of fish: the flowers are of a reddish colour on their outside, and yellowish within, of a very agreeable odour. It flowers in June, July, and August.

There are two sub-varieties of it, the Long Blowing and the Late Red.

The stems are stronger, the leaves, flowers, and heads of berries larger, and the corollas redder than in the Woodbine sort.

The Oak-leaved variety has sinuate leaves, cut like the oak, and smooth.

There is likewise a variety with variegated leaves.

In the tenth species the branches are slender, covered with a light green bark, and garnished with oval leaves of a thin texture, placed by pairs, sitting close to the branches; but those which are situated towards the end of the branches join at their base, so that the stalk seems as if it came through the leaves: the flowers are produced in whorled bunches at the ends of the branches; are white, and have a very fragrant odour, but of short duration, so that in about a fortnight they are entirely over; and soon after the leaves appear as if blighted and sickly, making an indifferent appearance the whole summer, which has rendered them less valued than the others. It flowers in May, and is a native of the South of Europe.

The variety which is the next in succession to the white, is the yellow, in which the shoots are much like those of the former, but have a darker bark: the leaves are also of a deeper green; the flowers of a yellowish red, and appear soon after the white; they are not of much longer duration, and are succeeded by red berries, containing one hard seed inclosed in a soft pulp, which ripens in the autumn.

Besides this, some mention other varieties, as the early red-flowering, the late red-flowering, and the evergreen red-flowering.

The eleventh grows naturally in Virginia, and many other parts of North America, but has been long cultivated in gardens by the title of Virginia Trumpet Honeysuckle. Martyn remarks, that of this there are two varieties, if not distinct species, one being much hardier than the other. The old sort, which came from Virginia, has stronger shoots; the leaves are of a brighter green; the bunches of flowers larger, and deeper coloured than in the other which came from Carolina. These plants have the appearance of the ninth sort, but the shoots are weaker than any of those, except the wild sort called Woodbine; they are of a purplish red colour, and smooth: the leaves are of an oblong oval shape inverted, and closely surrounding the stalk; of a lucid green on their upper side, but pale on their under: the flowers are produced in bunches at the end of the branches; these have long slender tubes, which are enlarged at the top, where they are cut into five almost equal segments: the outside of the flower is of a bright scarlet, and the inside yellow; they have a great appearance of the Honeysuckle, but are not so deeply divided, nor are the segments reflexed. They have no odour, but are cultivated for the beauty and long continuance of their flowers.

and their evergreen leaves. It flowers from May to August.

The twelfth species has strong branches, covered with a purple bark, which are garnished with lucid green leaves embracing the stalks, and continuing their verdure all the year: the flowers are produced in whorled bunches at the ends of the branches; there are frequently two and sometimes three of these bunches rising one out of another; they are of a bright red on their outside, and yellow within, of a strong aromatic flavour. This sort begins to flower in June, and there is a succession of flowers till the frost puts a stop to them, so that it is the most valuable of all sorts. It is a native of North America.

Culture.—All the sorts may be increased either by layers or cuttings, but the latter is the better practice. The layers should be made from the young shoots, and be laid down in the autumn or early spring, the straggling tops being removed, when by the following autumn they will have taken root, and should be cut off from the plants, being either planted where they are to remain, or into a nursery to be trained for standards, by fixing down stakes to the stem of each plant, to which the principal stalk should be fastened, all the others being cut off; training it to the intended height, when it should be shortened to force out lateral branches, and these be again stopped to prevent their growing too long. By constantly repeating this as the shoots are produced, they may be formed into a sort of standard; but if regard is had to their flowering, they cannot be formed into regular heads, as the constant shortening will destroy the flower-buds.

The cuttings should be taken from the strong shoots of the former summer, with three or four joints, and be planted in rows in a shady border, to the depth of two or three of them, a foot apart, and six inches from plant to plant. When they have taken good root in the autumn or spring following, they may be removed into the nursery, and be planted out in rows two feet distant, and a foot asunder in them, where they may be kept a year or two, till wanted for planting out where they are to remain.

The eighth sort may be raised from suckers, which it affords in plenty, by taking them off and planting them as above in the autumn in a rather moist soil.

Several of the sorts may likewise be increased by sowing the seed or berry in a bed of light mould in the autumn, to the depth of an inch. The plants rise in the first or second spring; and afterwards require the same management as the others.

The only culture which any of the sorts afterwards require is, in the upright sorts, to have their straggling shoots shortened, and the dead wood cut out; and those trained as climbers, to have their branches conducted in a proper manner upon their respective supports; and every year all rambling shoots reduced and trained as may be proper, so as to preserve them within due limits and order, except designed to run wild in their own rural way, especially those intended to climb among the branches of trees, shrubs, and bushes; those also intended to cover arbours and seats should be pruned and trained annually, laying the shoots along at their length, till they have covered the allotted space; shortening or clearing out all such stragglers as cannot be properly trained: also such of those sorts as are trained against walls, &c. must have an annual pruning and training, by going over them two or three times in summer, laying in some of the most convenient proper shoots, some at their length, shortening or retrenching others as necessary to preserve regularity, and the proper succession of flowers; being careful to train enough, at this time, of such as appear necessary to continue the bloom as long as possible; and in winter-pruning, all those left in summer, which may appear superfluous or unnecessary, should be turned out, shortening all such as are too long for the space allotted for them, especially all those with weak straggling tops, nailing in the remaining proper branches and shoots close to the wall, or other support.

They are all proper for plantations, both from the variety of their different growths, and the ornament and fragrance of their flowers; though the flowers of the upright kinds are not so showy as those of the trailers; but they exhibit an exceedingly agreeable variety.

The trailing species have, however, the greatest merit, not only in their numbers, but size, elegance, and odour, as well as in duration. The shrubs of all the sorts are, notwithstanding, proper to be introduced in shrubberies, the upright kinds to intermix as standards. The trailing kinds, whose branches are great ramblers, and, without support, trail along the ground, should generally be introduced as climbers, having stout stakes placed to each for them to climb upon, which they effect by ascending spirally round the support, to a considerable height; and also be placed to ascend round the stems of trees, and to climb among the boughs of the adjacent bushes, shrubs, and hedges, which they effect in a very agreeable manner, by interweaving their branches with them.

The climbers are likewise proper for training

against walls and arbours, &c., for the ornament and fragrance of their flowers, laying their branches in four or five inches asunder; thinning out the superabundant shoots annually, and training in some of the most robust for succession wood, either at full length, or shortened as most proper to fill the space.

The evergreen kinds are principally of the climbing tribe, and have much effect in their evergreen foliage and the elegance of their flowers, as well as in their long continuance in blow.

LOOKING-GLASS PLANT. See **HERITIERA**.

LOOSE-STRIPE. See **ANAGALLIS**.

LOPPING TREES, the practice of cutting off the boughs or branches of pollard or other trees. This work should be done with great care and attention, so as to prevent the decay of the trees.

Lopping of trees, at ten or twelve years growth, is said to preserve them much longer, and occasion the shoots to grow more into wood in one year than they do in old tops in two or three. When great boughs are ill taken off, it often spoils the trees; they should therefore always be spared, unless there is an absolute necessity. When they must be cut off, it should be close and smooth, and not parallel to the horizon, covering the wound with loam and horse-dung mixed, or some of Mr. Forsyth's composition, to prevent the wet from entering the bodies of the trees and destroying them.

There are various signs of the decay of trees; as, the withering or dying of their top branches; the wet entering at a knot; their being hollow, or discoloured; their making but poor shoots, and woodpeckers making holes in them.

Nothing is more injurious to the growth of timber-trees, than that of lopping or cutting off the great branches from them; as they grow better without it, and do not decay so soon.

The dead branches should however be removed.

The proper seasons for this sort of business, are the very early autumn and spring months.

All sorts of resinous trees, or such as abound with a milky juice, should be lopped very sparingly, as they are subject to decay when often lopped. The best season for lopping these trees is the latter end of summer or beginning of autumn; they then seldom bleed much, and the wounds are commonly healed over before the cold weather sets in.

Few sorts of ornamental trees should be much lopped, as it greatly injures their beauty and appearance. The only thing necessary, is to take off such straggling branches as may grow

VOL. II.

in an awkward or improper direction. See **PRUNING OF TREES**.

This sort of work is mostly performed with a saw, hedging-bill, or ax.

LORANTHUS, a genus containing a plant of the exotic kind for the stove.

It belongs to the class and order *Hexandria Monogynia*, and ranks in the natural order of *Aggregatæ*.

The characters are: that the calyx has the perianthium of the fruit inferior: margin entire, concave; of the flower superior, or the margin entire, concave: the corolla has six, oblong petals, revolute, equal: the stamina have six awl-shaped filaments, fastened to the bases of the petals, the length of the corolla: anthers oblong: the pistillum is an oblong germ, between the two calyxes, or inferior: style simple, the length of the stamens: stigma blunt: the pericarpium is an oblong berry, one-celled: the seed oblong.

The species cultivated is *L. Americanus*, American Loranthus.

Its branches are subdivided, leafy, smooth, pale green, brittle: the leaves petioled, opposite, entire, subcoriaceous, nerved, and pale: the petioles short, compressed, smooth: the racemes subdivided, terminating, with three-cornered branchlets; the last pedicels trifid, one-flowered: the flowers red.

It ramps over the highest trees in Jamaica, &c., especially the *Coccoloba grandifolia*, with the root adhering firmly to the bark like *Mistletoe*.

Culture.—This plant may be increased by sowing the seeds as soon as they are fully ripened, in pots of light rich earth, being kept in a mild hot-bed until the beginning of the autumn, when they must be plunged in the bark hot-bed of the stove, being afterwards treated as other tender plants of the same kind.

It affords variety in stove collections.

LORDS AND-LADIES. See **ARUM**.

LOTE-TREE. See **CELTIS**.

LOTUS, a genus containing plants of the herbaceous and under-shrubby kind.

It belongs to the class and order *Diadelphica Decandria*, and ranks in the natural order of *Papilionaceæ* or *Leguminosæ*.

The characters are: that the calyx is a simple umbel: perianthium one-leafed, tubular, half-five-cleft: teeth acute, equal, erect, permanent: the corolla papilionaceous: banner roundish, bent down; claw oblong, concave: wings roundish, shorter than the banner, broad, converging upwards: keel gibbous below, closed above, acuminate, ascending, short: the stamina have diadelphous filaments, simple and nine-cleft, ascending, with broadish tips: anthers small, simple: the

L

pistillum is a columnar germ, oblong : style simple, ascending : stigma an inflected point : the pericarpium is a legume cylindric, stiff and straight, stuffed, longer than the calyx, many-celled, two-valved : the seeds several and cylindric.

The species cultivated are : 1. *L. tetragonolobos*, Winged Bird's-foot Trefoil ; 2. *L. jacobaeus*, Dark-flowered Bird's-foot Trefoil ; 3. *L. creticus*, Silvery Bird's-foot Trefoil ; 4. *L. hirsutus*, Hairy Bird's-foot Trefoil ; 5. *L. Dorycnium*, Shrubby Bird's-foot Trefoil.

The first has an annual root : the stems several, decumbent, upright, about a foot long, having at each joint a ternate leaf : the leaflets ovate : the stipules of the same shape : peduncles axillary, alternate, from two to three inches long, each sustaining one (sometimes two) large red flowers at the top, with three leaves just under the flower. The wings are very dark purple, appearing to be black at the end : the legume thick, with four broad undulating wings : the seeds sub-globular, the size of a small pea, smooth, pale or livid purple, without spots. It flowers in June and July, and the seeds ripen in autumn. It is a native of Sicily.

It was formerly cultivated as an esculent plant, for the green pods, which are said to be still eaten in some of our northern counties, but they are very coarse. It is now chiefly cultivated in flower-gardens for ornament.

The second species has a slender woody stem, from two to three feet high, sending out many slender herbaceous branches : the leaves sessile, hoary : leaflets narrow, white : the flowers axillary from the upper part of the stem, four or five, on very slender peduncles, of a yellowish deep purple colour : the pods taper, slender, little more than an inch long, containing five or six small roundish seeds. It is a native of the Cape Verd Islands, flowering all the summer and autumn, and many times a great part of the winter.

The third species rises with slender stems which require support, from three to four feet high, sending out a few side branches. At each joint is a neat silvery ternate leaf, with two appendages or stipules : the peduncles axillary, from two to three inches long, sustaining heads of yellow flowers, which part in the middle, each head containing four or six flowers : these appear in May, June, and July, and are succeeded by long taper pods filled with roundish seeds, which ripen in the autumn. It is a native of Spain and the Levant.

The fourth species has a perennial stalk three feet high : when the roots are large, they fre-

quently send up several of these stalks, especially if the old ones be cut down : they are hairy, and divide into several branches : the leaves are ternate, hoary, with two stipules : the flowers in heads on long axillary peduncles : the calyxes very hairy : the corollas dirty white, with a few marks of pale red : the pods short, thick, chestnut-coloured, containing several roundish seeds. It is a native of the South of Europe, flowering from June to August.

The fifth species rises with weak shrubby stalks three or four feet high, sending out many slender branches, thinly set with small hoary leaves, having five leaflets, spreading like the fingers, and sessile : the flowers at the extremity of the branches in small heads. They are very small and white, appear at the end of June, or in July, continue to September, and are succeeded by short pods, containing two or three small round seeds. It is a native of the South of Europe.

Culture.—The first sort is raised by sowing the seed annually in spring, in the open ground, in the places where the plants are to remain, in patches in different parts, of five or six seeds in each, half an inch deep. The plants soon come up, which, remaining in the same place for flowering, require only occasional weeding, being either suffered to trail, according to their natural growth, or tied up to sticks.

The other sorts may be increased by seeds and cuttings.

The seeds should be sown in pots of light earth or in a moderate hot-bed ; and when the plants are about three inches high be planted out in separate small pots of light rich earth, giving water, and placing them in the shade till fresh-rooted.

The cuttings of the young stalks and branches may be planted any time in the spring or summer, in beds or pots of rich mould, giving shade and water. They emit roots, and form plants in a few weeks, but may be greatly facilitated by covering them close with hand-glasses till they begin to shoot at top ; then they should be gradually inured to the air, and soon after be transplanted into separate pots.

The young green seed-pods of the first sort were formerly dressed and eaten as peas, or in the manner of kidney-beans.

The other kinds effect an agreeable variety in collections of green-house plants, both in their foliage and flowers. They all require shelter from frost, the two first in particular ; the two last are somewhat hardier, and sometimes succeed in the full ground all the year, in warm dry situations. A few plants should however con-

stantly be kept in the pots, to be protected in the winter season.

LOVAGE. See *LIGUSTICUM*.

LOVE-APPLE. See *SOLANUM LYCOPERSICUM*.

LOVE-LIES-BLEEDING. See *AMARANTHUS CORDATUS*.

LUNARIA, a genus containing plants of the herbaceous annual and perennial kinds.

It belongs to the class and order *Tetradynamia Siliculosa*, and ranks in the natural order of *Siliculosæ* or *Cruciformes*.

The characters are: that the calyx is a four-leaved perianthium, oblong: leaflets ovate-oblong, blunt, converging, deciduous, of which the two alternate ones are gibbous and bagged at the base: the corolla four-petalled, cruciform: the petals entire, blunt, large, the length of the calyx, ending in claws of the same length: the stamina have six awl-shaped filaments; four the length of the calyx, two a little shorter: anthers from upright, spreading: the pistillum is a pedicelled germ, ovate-oblong: style short: stigma blunt, entire: the pericarpium is an elliptic silicle, flat, entire, upright, very large, pedicelled, terminated by the style, two-celled, two-valved: partition parallel and equal to the valves, flat: the seeds some kidney-shaped, compressed, marginal, in the middle of the silicle: the receptacles filiform, long, inserted into the lateral sutures.

The species cultivated are: 1. *L. rediviva*, Perennial Honesty; 2. *L. annua*, Annual Honesty, Moor-wort, or Satin-flower; 3. *L. Ægyptiaca*, Egyptian Honesty.

The first is a very large plant: the root is perennial, white: stem from three to four feet high, upright, simple, channelled, green tinged with purple, hirsute: the lower leaves opposite; upper alternate, on long petioles, smooth or rough-haired, cordate, unequally serrate, nerved, acuminate, near a span long, and three or four inches wide: the flowers terminating, on long slender peduncles, often bifid and trifid, of a white purple colour, and odorous. They have two glands on each side between the longer stamens and the style, and one between the style and each shorter stamen, which accounts for the bagging of the perianthium. It is a native of the South of France, &c.

The second species has a biennial, knobbed root: the stem smaller than the first; upright, branched, hirsute, round, half a yard high: the leaves are rough haired, the floral ones almost always opposite, sessile: stem-leaves petioled, much smaller than those of the first sort, cordate, dull green, and serrate: the flowers are of a purplish violet or blue-purple colour, and inodorous.

It is a native of Germany. Both these species flower in May and June.

The seed-vessels, when fully ripe, become transparent, and of a clear shining white like satin; whence the name of Satin-flower.

The third is an annual plant, with a smooth branching stalk little more than a foot high: the leaves are unequally pinnate: leaflets differing in size and form; some almost entire, others cut at their extremities into three parts; they are smooth, and of a lucid green: the flowers stand each upon pretty long slender peduncles, which come out from the side, and also at the end of the branches, in loose small clusters; they are of a purple colour, and are succeeded by oblong compressed pods, which hang downward, and when ripe are of a feuillet-mort colour. It is a native of Egypt, flowering here, in June and July.

Culture.—These plants may be raised by sowing the seed in a shady border, or, which is better, in patches in the situations where they are to remain, in the autumn, keeping the plants afterwards properly thinned out and free from weeds. They may likewise be sown in the early spring; but the former is the better season, as the plants rise stronger. The last sort should have an open situation. When sown in beds, the perennial sort should be set out where they are to remain, in the following autumn after being sown.

They all afford ornament and variety in the borders and clumps of pleasure-grounds, in which the first sort should be placed more backward.

LUPINUS, a genus containing plants of the hardy herbaceous annual and perennial flowery kinds.

It belongs to the class and order *Diadelphina Decandria*, and ranks in the natural order of *Papilionaceæ* or *Leguminosæ*.

The characters are: that the calyx is a one-leaved perianthium, bifid: the corolla papilionaceous: banner cordate-roundish, emarginate, bent back at the sides, compressed: wing subovate, almost the length of the banner, not fastened to the keel, converging below: keel two-parted at the base, sickle-shaped upwards, acuminate, entire, the length of the wings, narrower: the stamina have ten filaments, united, somewhat ascending, distinct above: anthers five, roundish, and as many oblong: the pistillum is an awl-shaped germ, compressed, villose: style awl-shaped, ascending: stigma terminating, blunt: the pericarpium is a large legume, oblong, coriaceous, compressed, acuminate, one-celled: the seeds several, roundish and compressed.

The species cultivated are: 1. *L. albus*, White Lupine; 2. *L. varius*, Small Blue Lupine; 3. *L. angustifolius*, Narrow-leaved Blue Lupine; 4. *L. hirsutus*, Great Blue Lupine; 5. *L. luteus*, Yellow Lupine; 6. *L. perennis*, Perennial Lupine.

The first has a thick upright stalk about two feet high, dividing towards the top into several smaller hairy branches: the leaves are digitate, composed of seven or eight narrow oblong leaflets, joining at the base; they are hairy, of a dark grayish colour, and have a silvery down: the flowers are produced in loose spikes at the end of the branches; they are white and sessile: the legumes are straight, hairy, about three inches long, containing five or six seeds, which are roundish, flattened like a lens, extremely smooth and even, perfectly white without any spots, smaller than most of the others. It flowers in July, and the seeds ripen in the autumn: growing naturally in the Levant.

The second species is an annual plant, with a firm, straight, channelled stalk near three feet high, divided towards the top into several branches: the leaves are digitate, composed of five, six, or seven oblong or linear leaflets, which join at their base, and are hairy: the flowers are produced in spikes at the end of the branches, standing round the stalk in half whorls; they are of a light blue colour. It is a native of the South of France, &c. flowering in July.

The third has much the appearance of the second sort, but the stalks rise higher: the leaves have more leaflets, and stand upon longer foot-stalks: the leaflets are blunt: the seeds are variegated; and, according to Linnæus, they are linear, and the flowers blue. Ray describes it as more upright, and much taller, being eighteen inches high, and as tall as the first. It is a native of Spain, &c.

The fourth species is also an annual plant, which rises with a strong firm channelled stalk, from three to four feet high, covered with a soft brownish down, dividing upward into several strong branches, garnished with digitate leaves, composed of nine, ten, or eleven wedge-shaped hairy leaflets, which are narrow at their base, where they join the foot-stalk, but enlarge upward, and are rounded at the top, where they are broadest: the foot-stalks of the leaves are three or four inches long: the flowers are placed in whorls round the stalks above each other, forming a loose spike, which proceeds from the end of the branches; are large, and of a beautiful blue colour, but have no scent: they appear in July, and the seeds ripen in autumn: the pods are large, almost an inch broad, and

three inches long; inclosing three large roundish seeds, compressed on their sides, very rough and of a purplish brown colour. It is a native of the South of Europe.

There is a variety with flesh-coloured flowers, commonly called *Rose Lupine*.

The fifth has a stem a foot high, branching: the leaves are digitate, composed of seven, eight, or nine narrow hairy leaflets, nearly two inches long: the flowers are yellow, odorous, in loose spikes at the end of the branches, composed of several (six or seven) whorls, with spaces between them, and about five flowers in each, terminated by three or four flowers, sitting close at the top; these are succeeded by ovate flattish hairy pods, about two inches long, standing erect, and inclosing three, four, or five roundish seeds, a little compressed, yellowish white, variegated with dark spots. It is a native of Sicily, flowering in June and July.

The sixth has a perennial creeping root, from which arise several erect channelled stalks a foot and a half high, sending out two or three small side branches, garnished with digitate leaves, composed of from five to ten or eleven narrow spear-shaped leaflets, which join at their base, and stand upon very long foot-stalks, having a few hairs on their edges: the flowers grow in long loose spikes, which terminate the stalks, and are placed without order on each side; they are of a pale blue colour, and on short peduncles; appearing in June, and the seeds ripening in August, which are soon scattered if they are not gathered when ripe; for, after a little moisture, the sun causes the pods to open with elasticity, and cast out the seeds to a distance. It is a native of Virginia.

Culture.—These plants may be readily raised by sowing the seeds in patches in the borders, with other annuals in the spring, where they are to remain; thinning them afterwards where they are too close, and keeping them clean from weeds. In order to have a succession of flowers, they should be sown at different times, as in April, May, and June. The seed of those only which are first sown ripens well.

In order to have good seed of the fourth kind, some seeds should be sown on a sunny border under a wall, or in pots placed under frames, the plants in the latter case being turned out and planted with balls of earth about them in the spring.

They are all useful plants for producing variety, in the borders, clumps, and other parts. The last sort should be sown at many different times.

LUXURIANT PLANTS, a term in gardening; signifying such as become greatly aug-

mented in growth beyond their common natural state, and which rarely acquire that degree of perfection which is the case with those of more moderate growths. This sometimes happens from excess of nourishment, and sometimes from the nature of the plants.

It is produced differently; sometimes prevailing in the whole plant, sometimes in particular parts, as in some of the shoots, and frequently in the flowers.

The first may be considered such as shoot much stronger than plants of the same species generally do, and happens both in herbaceous plants and trees, &c. which never attain perfection so soon as the more moderate growers: thus many sorts of esculent plants which shoot luxuriantly to leaves and stalks, &c. as cucumbers, melons, cabbages, cauliflowers, turnips, radishes, beans, peas, &c., never arrive so soon to perfection as those of moderate growth; and such plants as appear to be naturally of themselves of a very luxuriant nature, are very improper to stand, from which to save seed for future increase.

This is also the case in fruit-trees; as such as are very luxuriant shooters are much longer before they attain a bearing state than those of middling growth; and they never bear so plentifully, or have the fruit attain such perfection. This luxuriance is frequently acquired by unskilful pruning, especially in wall-trees, &c., as it is often the practice, when wall or espalier trees assume such a growth, to cut all the shoots short; by which, instead of reducing the tree to a moderate state of shooting, it has its vigour increased, as too considerable shortening of strong shoots promotes their throwing out still stronger, and producing more abundant or superfluous wood. Therefore, in pruning very luxuriant espalier and wall-fruit trees, they should be assisted somewhat in their own way, as it were, by training in plenty of shoots annually for a year or two, to divide the redundancy of sap; or in the summer and winter prunings, always leaving them rather thicker than in the common practice, and mostly at full length, unless it be necessary to shorten such as are of very considerable length, or in some particular part of the tree, to force out a supply of wood to fill a vacancy. Some sorts of fruit-trees should indeed never be generally shortened in the common course of pruning, except in casual very extended irregular growths, or occasionally for procuring a supply of wood as mentioned above. This is particularly necessary in apples, pears, plums, cherries, and fig-trees; for, if general shortening was to be practised in these sorts, they would continue shooting every year so luxuriantly to wood, that

they would never form themselves into a proper bearing state: even in those trees where shortening is necessarily practised in winter, in most of the annual supplies of shoots, as in peaches, nectarines, &c., in cases of luxuriant growth, it should be very sparingly performed, the general shoots not being cut very short, and some of the most vigorous left almost or quite at the full length.

This is the proper method to reduce luxuriant trees to a moderate growth, and to a bearing state; as by training the shoots thicker, and leaving them longer, and continuing it for a year or two, the redundant sap having greater scope to divide itself, cannot break out with that luxuriance, as when it has not half the quantity of wood to supply with nourishment, as in the case of short pruning. See *ESPALIER, WALL-TREES, and PRUNING.*

This state seldom occurs with any continuance in standard-trees, where permitted to take their natural growth, except in casual straggling shoots, which should always be taken out.

Over luxuriant shoots are mostly met with in trees and shrubs; but require more particularly to be attended to in the culture of the fruit tree kind, especially those of the wall and espalier sort, which undergo annual pruning.

They are such as shoot so vigorously in length and substance, as greatly to exceed the general growth of those usually produced on the same kind of plant or tree, and are sometimes general, but in other cases only happen to particular shoots in different parts of a tree, &c. They are discoverable by their extraordinary length and thickness, and by their vigour of growth, which always greatly impoverishes the other more moderate shoots in their neighbourhood, and likewise the fruit, &c., as well as often occasions a very irregular growth in the respective trees. Such shoots frequently occur in wall and espalier fruit-trees, and are the effects of injudicious pruning. When they are in general wholly so, they should be managed as directed above; but when only in particular shoots here and there in a fruit or other tree or shrub under training, such shoots being of such a very luxuriant nature as to draw away the nourishment, at the expense of the adjacent moderate shoots, and which, by their vigorous irregular growth, cannot be trained with any degree of regularity; they should for the most part, as soon as discoverable, in the summer or winter prunings, be cut out, taking them off as close as possible to the part of the branch whence they originate, that no eye may be left to shoot again; unless such a shoot should rise in any part of a tree or shrub, where a further

supply of wood may be requisite; in which case it may be retained, and shortened as convenient, to force out a supply of more shoots laterally to fill the vacancy.

When it prevails in other trees and shrubs than those of the fruit kind, they should have occasional attention, pruning them in regular order in their younger advancing growth, or afterwards occasionally in particular sorts, as may be necessary; observing, in either, when any straggling shoots, &c. assume a very luxuriant rambling growth, greatly exceeding the other general branches, that they be more or less reduced, or cut entirely away close to their origin, as may be most expedient, according to the nature of growth of the trees or shrubs, either in summer or winter, &c.

Most double flowers may be considered as luxuriant, especially such as have the cup or corolla multiplied, or so augmented in the number of their leaves, or flower-petals, inward, as to exclude some part of the fructification, as the same thing occurs in flowers as in esculent plants and fruit-trees, from their over luxuriant growth; for, as the flower is designed for perfecting the fruit and seed, when the petals are multiplied to the diminution of the stamina, &c. no impregnation ensues, and of course no fruit or seed is produced.

In the double varieties of most kinds of flowers produced on ornamental flowering plants, this luxuriance is generally considered as a superior degree of perfection; and has different modifications.

The highest degree of this sort of luxuriance is met with in carnations, anemones, ranunculuses, the poppy, lychnis, peony, narcissus, violet, and some others.

LYCHNIS, a genus containing plants of the hardy, herbaceous, flowery, perennial kind.

It belongs to the class and order *Decandria Pentagynia*, and ranks in the natural order of *Caryophyllei*.

The characters are: that the calyx is a one-leaved perianthium, oblong, membranaceous, five-toothed, permanent: the corolla has five petals: claws the length of the calyx, flat, margined: border often cloven, flat: the stamina have ten filaments, longer than the calyx, alternately shorter, each of these fixed to a claw of each petal: anthers incumbent: the pistillum is a subovate germ: styles five, awl-shaped, longer than the stamens: stigmas reflex against the sun, pubescent: the pericarpium is a capsule approaching to an ovate form, covered, one-, three-, or five-celled, five-valved: the seeds very many, and roundish.

The species cultivated are: 1. *L. chalcedonica*, Scarlet Lychnis; 2. *L. Flos cuculi*, Red-flower-

ed Lychnis, Meadow Pink, or Ragged Robin; 3. *L. coronata*, Chinese Lychnis; 4. *L. viscaria*, Viscous Lychnis, or Catchfly; 5. *L. diurna*, Rose-flowered Lychnis, Wild Red Campion, or Red Bachelor's Buttons; 6. *L. vespertina*, White-flowered Lychnis, Wild White Campion, or White Bachelor's Buttons.

The first has a perennial root: the stems three feet high, upright, stiff, round, jointed, hairy: at every joint are two large leaves of a brownish green colour: the flowers terminating in a large flat-topped tuft, consisting of several bundles: the corolla is of a scarlet or bright red orange colour, varying to white, blush, and variable, that is, pale red, growing paler till it becomes almost white. It is a native of Russia, &c.

Besides its varying as above, there is a variety with very double flowers of a beautiful scarlet colour: it has a perennial root, from which arise two, three, or four stalks, according to the strength of the roots, which in rich moist land grow upwards of four feet high; the stalks are strong, erect, and hairy, being garnished the whole length with spear-shaped leaves sitting close to the stalks, placed opposite; and just above each pair of leaves there are four smaller leaves standing round the stalk: the flowers are produced in close clusters sitting upon the top of the stalk: when the roots are strong, the clusters of flowers are very large, and make a fine appearance, coming out the latter end of June, and in moderate seasons continue near a month in beauty. The stalks decay in autumn, and new ones arise in the spring following.

The second has also a perennial root, brownish white, subacrid: the stems from one to three feet high, upright, somewhat angular and grooved, swelled at the joints, purplish: they are procumbent, and become upright at the time of flowering: the stem-leaves opposite, connate, lanceolate, keeled, upright, smooth: the peduncles opposite, with one generally between them: the calyx ten-angled, of a deep purple colour: the corolla pink or purplish red, varying sometimes to white: the border of the petals dividing into four segments, of which the two outer are shorter and narrower: the claws have two small spear-shaped teeth at the top: the capsule one-celled, the mouth having five teeth which turn back: the seeds flattish, rugged, of a brown ash-colour. It is a native of most parts of Europe, flowering in May and June.

In the third the whole plant is smooth: the stem simple, round, upright, a foot high: the leaves opposite, embracing, oblong-ovate, acute, entire, an inch or a little more in length: the flowers aggregate, about three, sessile: the calyx is ten-angled: the petals are gashed, cre-

nate-multifid: the filaments the length of the tube of the corolla, filiform: the germ superior: styles five, much shorter than the tube of the corolla. It is a native of China and Japan, flowering in June and July.

The fourth species has long, narrow, grass-like leaves, which come out from the root without order, sitting close to the ground; between these come up straight single stalks, which in good ground rise a foot and half high; at each joint of the stalk come out two leaves opposite, of the same form as the lower, but decreasing in their size upwards; under each pair of leaves, for an inch in length, there sweats out of the stalk a glutinous liquor, which is almost as clammy as birdlime, so that ants and other insects which happen to light upon these places, or attempt to creep up to the flowers, are fastened to the stalk; whence the title of Catchfly: the root is perennial, yellowish on the outside, white within: the stem round, not grooved, smooth, being terminated by a cluster of purple flowers, and from the two upper joints come out on each side of the stalk a cluster of the same flowers, so that the whole forms a sort of loose spike: these appear in the beginning of May, and the single flowers are succeeded by roundish seed-vessels, which are full of small angular seeds, ripening in July. It is a native of most parts of Europe.

The fifth has likewise a perennial root, the thickness of the little finger, white, of a slightly acrid and bitter taste, furnished with numerous fibres: the stalks are several, upright, from one to three feet high, round, hirsute, jointed, purple, the joints swelled: the uppermost branches forked: the leaves opposite, connate, ovate-acuminate, hirsute, slightly nerved: the calyx is hairy, striated, purple, five-toothed; in the female more turgid: the petals purple, obcordate: at the bottom of the lamina or broad spreading part are two or four small upright white blunt appendices: the germ is ovate, surrounded by a nectary at the base: the capsule one-celled, with ten teeth at the mouth: seeds gray, somewhat rugged. It is a native of many parts of Europe.

There is a variety with double flowers, cultivated in gardens by the name of Red Bachelor's Buttons, which is an ornamental plant, and continues long in flower.

The sixth species has the stalks branched out much more than in the fifth sort, being weaker and more flaccid: the leaves are longer and more veined: the flowers stand singly upon pretty long peduncles, and are not produced in clusters as in that; it is very hairy, the calyx is more swollen, and it flowers a month after it.

And Dr. Withering remarks, that the petals on the male plant have the laminae divided down to the claws, but in the female they are only cloven half way down. Dr. John Sibthorp also states that the capsules in the fifth are roundish, and that its scentless flowers stand open through the day; while this has conical capsules, and its odoriferous flowers open only towards evening. This also prefers a dry soil, while that spreads in a moist one. It is common in Siberia.

• There are varieties with purple or blush-coloured flowers; with quadrid petals; with hermaphrodite flowers; with double flowers, cultivated in gardens by the name of Double White Bachelor's Buttons.

Culture.—They may be increased with facility in the single sorts by seed, and parting the roots; and in the doubles by dividing or slipping the roots, and sometimes by cuttings of their stalks.

The seed should be sown in the early spring, as in March, in a bed or border of light earth, in an eastern aspect, each sort separate, raking them in lightly, or they may be sown in small drills. The plants come up in two or three weeks, when they should have occasional waterings and hand weedings: and when the plants are two or three inches high, be planted out in beds or borders, in rows six inches asunder, watering them till fresh rooted, letting them remain till the autumn or following spring, when they should be transplanted where they are to remain.

Both the single and double may be increased by slipping the roots; but it is more particularly applicable to the double sort, as they cannot with certainty be obtained from seed: the season for performing this work is the autumn, after the stalks decay, when the whole root may either be taken up, and divided into as many slips as are furnished with proper root-fibres, or the main root stand, and as many of the outer offsets as seem convenient be slipped off: these slips, when strong, should be planted at once where they are to remain; but when rather small and weak, it is better to plant them in nursery-rows, half a foot asunder, to remain a year, and then transplant them for good where they are to stand.

The planting of cuttings of the stalks is mostly practised for the double scarlet sort, when it increases but sparingly by offsets of the root. It is performed in summer, when the stalks are well advanced in growth, but before they flower, or have become hard and woody. Some of them should be cut off close to the bottom, and divided into lengths of from three to five joints, planting them in an easterly border of rich moist loamy earth, two-thirds of

their length into the ground, leaving only one joint or eye out, watering them directly, and repeating it occasionally with necessary shade in hot weather. They will be well rooted, and form proper plants for transplanting in the autumn. If the cuttings, as soon as planted, are covered down close with hand-glasses, it will greatly promote their rooting, so as to form stronger plants before the winter season comes on.

The only culture they require afterwards is clearing them from weeds in summer, and supporting with stakes them which need it, cutting down and clearing away the decayed stalks in the autumn.

Of the third sort, as being rather more tender, some plants should be planted in pots, for moving under the protection of a frame or greenhouse in the winter season.

They are all very ornamental for the pleasure-ground, particularly the doubles, and prosper in any common soil, remaining in all weathers unhurt, being of many years' duration in root; and, when of some standing, send up many stalks every spring, terminated by numerous flowers, making a fine appearance in summer. The Scarlet Double *Lychnis* claims the preference, though the single scarlet sort is also very showy. And all the other species in their respective double-flowered states are ornamental. They are all kept in the nurseries for sale. In planting out, the tallest growers should be placed the most backward, and the others more towards the front.

LYCIUM, a genus containing plants of the shrubby exotic kind.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Lauridæ*.

The characters are: that the calyx is a sub-quinquefid perianthium, obtuse, erect, very small, permanent: the corolla monopetalous, funnel-form: tube cylindric, spreading, incurved: border five-parted, obtuse, spreading, small: the stamina have five awl-shaped filaments, from the middle of the tube, shorter than the corolla, closing the tube with a beard: anthers erect: the pistillum is a roundish germ: style simple, longer than the stamens: stigma bifid, thickish: the pericarpium is a roundish berry, two-celled: the seeds several and kidney-form: the receptacles convex, affixed to the partition.

The species are: 1. *L. Afrum*, African Box-thorn; 2. *L. barbarum*, Willow-leaved Box-thorn; 3. *L. Europæum*, European Box-thorn; 4. *L. Tartaricum*, Tartarian Box-thorn.

The first rises with irregular shrubby stalks ten or twelve feet high, sending out several

crooked knotty branches, covered with a whitish bark, and armed with long sharp spines, upon which grow many clusters of narrow leaves; these thorns often put out one or two smaller on their sides, which have some clusters of smaller leaves upon them: the branches are garnished with very narrow leaves an inch and a half long, and at the base of these come out clusters of shorter and narrower leaves: the flowers come out from the sides of the branches, standing upon short foot-stalks, and are of a dull purple colour: the berry is of a yellowish colour when ripe, very dark red, inclosing several hard seeds. It usually flowers in June and July, and the seeds ripen in the autumn; but frequently a few flowers come out in all the summer months. It is a native of the Cape.

The second species is a weak shrub, nodding and decumbent unless supported: the bark of the branches whitish: the flowers from each bud from two to five, each on its proper peduncle. It differs from all the other sorts in having the mouth of the calyx two-lobed, or sometimes three-lobed: the border of the corolla spreading, with the throat pale streaked with black, and purple or pale red within. It is a native of Europe, Asia, and the Cape, flowering from May to October.

There are several varieties. The first has a shrubby stalk seven or eight feet high, sending out several irregular branches, armed with strong spines, and furnished with short thick leaves: the flowers, which come out from the side of the branches are small and white. They appear in July and August, but do not produce seeds in this climate.

The second has the stalk four or five feet high, sending out many irregular branches, covered with a very white bark, and armed with a few short spines: the leaves are about three inches long, and one inch broad in the middle, alternate, pale green. The flowers appear in June and July, and are succeeded by small round berries that ripen in the autumn, when they become as red as coral.

The third rises with weak irregular diffused branches to a great height, requiring support: some of these branches have in one year been upwards of twelve feet long: the lower leaves are more than four inches long, and three broad in the middle; they are of a light green and a thin consistence, placed without order on every side the branches. As the shoots advance in length, the leaves diminish in size, and towards the upper part are not more than an inch long and a quarter of an inch broad; sitting close to the stalks on every side. The flowers come out singly at every joint towards the upper part of

the branches, on short slender peduncles, and are of a pale colour with short tubes; the brims are spread open, broader than either of the former sorts, and the style is considerably longer than the tube of the corolla. It flowers in August, September, and October, retaining its leaves till November, and is a native of China.

The third is able to stand upright without support; differing from the above in having the leaves, though lanceolate, not flat but oblique or flexuose: the branchlets flexuose, not rendered angular by a line running down from the petiole; the surface not smooth, but subtomentose; and finally, spines from every bud. It differs from the first in having lanceolate leaves, and round flexuose branchlets. It is a native of the South of Europe.

The fourth species is an elegant shrub, on account of the whiteness of the branches, rods, or twigs, which are many, a foot or eighteen inches long or more, branched, ascending: the spines alternate, awl-shaped, rigid, spreading, white or yellowish, surrounded with leaves and flowers at the base: the leaves are sessile, fleshy, blunt: flowers from the upper part of the twigs among the leaves, two or three to each spine, on short peduncles: the berries the size of a currant, black and succulent. It is a native of Tartary. It differs from the third sort in size, and the colour and form of the flower.

Culture.—These plants may all be increased by seeds, cuttings, or layers.

The seeds should be sown in the autumn soon after they are ripe, in pots, being plunged into an old tan-bed in winter, and covered with the glasses in frosty weather; but in mild weather be open to receive moisture; in the following spring the pots should be plunged into a moderate hot-bed, to bring up the plants, which must be inured to bear the open air as soon as the danger of frost is over, and when they are three inches high, be shaken out of the pots, and each planted in a small separate pot filled with loamy earth, being placed in the shade till they have taken new root, when they may be removed to a sheltered situation, to remain till the autumn, when they should be either removed into the greenhouse, or placed under a hot-bed frame, to shelter them from hard frost. They must at first be kept in pots, and treated in the same way as myrtles, and other hardy green-house plants; but when they are grown strong, a few of them may be planted out in the open ground in warm situations, where they stand moderate winters, but are commonly destroyed by hard frosts.

The cuttings should be made from the young shoots, and be planted in a shady border in July,
VOL. II.

being duly watered; and when they have taken root, be treated in the same way as the seedling plants. This is the usual mode of increasing them, as some sorts never produce seeds in this climate.

In the third sort the cuttings should be planted in the spring, in an eastern border; and the plants should not be removed till the autumn, when they may be planted to cover walls, as the branches are too weak to support themselves.

The third variety may also be increased by dividing and planting its creeping roots.

The layers must be made from the young branches, and be laid down in the spring; and when rooted in the autumn, taken off, and managed as in the other methods.

The hardy sorts afford variety in warm situations in the open ground, and the other sorts among green-house collections.

LYSIMACHIA, a genus containing plants of the hardy herbaceous biennial and perennial kinds.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Rotaceae*.

The characters are: that the calyx is a five-parted perianthium, acute, erect, permanent: the corolla one-petalled, wheel-shaped: tube none: border five-parted, flat: divisions ovate-oblong: the stamens have five awl-shaped filaments, opposite to the divisions of the corolla: anthers acuminate: the pistillum is a roundish germ: style filiform, the length of the stamens: stigma obtuse: the pericarpium is a globular capsule, mucronate, one-celled, ten-valved (five-valved): the seeds very many, and angular: the receptacle globular, very large, dotted. (free.)

The species cultivated are: 1. *L. Ephemerum*, Willow-leaved Loose-strife; 2. *L. dubia*, Purple-flowered Loose-strife; 3. *L. stricta*, Upright Loose-strife.

The first has a perennial root: the stems several, upright, more than three feet high: the leaves narrow, smooth, and at the base of these come out short side branches, with smaller leaves of the same shape: the flowers are produced in a long close upright spike, at the top of the stalk: the corolla is white: the stamens longer than the corolla. It is very distinct from the second sort by its size, five-valved capsules, white flowers, and leaves without dots. It is a native of Spain, flowering from July to September.

The second species is an annual (biennial) plant, too tender for the open air of this climate: it agrees with the first sort in habit, structure, and glaucous colour: it has no dots

under the leaves: the petals are acuminate, a little longer than the calyx, converging, and deep red: the stamens are longer than the corolla, with brown anthers: and the flowers sessile in a spike. It is nearly allied to the first sort, and is a native of the Levant, flowering in July and August.

The third has the stem erect, four-cornered, smooth: the leaves quite entire, acute, smooth, dotted: the racemes simple: the pedicels in a sort of whorl, filiform, an inch long: the bractes lanceolate, very short: the divisions of the calyx lanceolate, smooth, dotted with red: the petals three times as long as the calyx, yellow, with red stripes and dots, and two dark-red spots: the stamens shorter than the corolla. It is a native of North America, flowering in July and August.

Culture.—These may all be readily increased either by sowing the seeds in the autumn, as soon as they are fully ripened, on a moist border, with an eastern aspect; or by parting the roots, and planting them out at the same season, in the same situations.

The plants should afterwards be kept clean, and in the first method removed into the situations where they are to remain in the autumn.

In the second sort the seeds should be sown on a hot-bed.

The third sort is increased by planting the bulbs thrown out from the axils of the leaves.

They all afford ornament and variety in the borders and other parts of pleasure-grounds.

LYTHRUM, a genus containing plants of the hardy herbaceous perennial kind.

It belongs to the class and order *Dodecandria Monogynia*, and ranks in the natural order of *Calycanthemæ*.

The characters are: that the calyx is a one-leaved perianthium, cylindric, striated, with twelve teeth, alternately smaller: the corolla has six oblong petals, bluntish, spreading, with the claws inserted into the teeth of the calyx: the stamina have twelve filiform filaments, the length of the calyx; the upper ones shorter than the lower: anthers simple, rising: the pistillum is an oblong germ: style awl-shaped, the length of the stamens, declined: stigma orbiculate, rising: the pericarpium is an oblong acuminate capsule, straight, two-celled or one-celled: the seeds numerous and small.

The species cultivated is *L. Salicaria*, Common or Purple Willow-herb.

Other species may be introduced into cultivation.

It has a perennial root, thick branched, somewhat woody, widely extended: the stem from two or three to four or six feet high, up-

right, tinged with red, below smooth and four-cornered, above pubescent and five-cornered; corners sharp, membranaceous, rugged: the upper branches scattered, lower opposite, four-cornered, rugged, and slightly downy, upright, shortish, numerous: the leaves sessile, embracing, about three inches long, smooth above, underneath slightly downy, somewhat rugged, veined, spreading, all opposite, or all alternate, or the lower opposite, and the upper alternate: the flowers in clusters, placed at a little distance from each other, in the axils of the leaves, each consisting of about eight flowers (six or twelve), together forming a long leafy spike. It is a native of most parts of Europe, flowering late in the summer.

There are several varieties; in the first of which the stalks are upright and branching, three feet high: the leaves cordate ovate, an inch long, and three quarters of an inch broad, downy, and placed by threes: the flowers in long spikes, disposed in thick whorls, with spaces between each; they are of a fine purple colour. It is smaller than the common sort, much more downy, and the leaves broader. It often varies with three leaves to a joint; in which case the stem is six-cornered; and sometimes even with four leaves at a joint. And Linnæus mentions a variety, in which the stem is a foot high and simple: the leaves alternate, cordate-lanceolate, sessile: the flowers from each upper axil, solitary, and sessile.

There is also a variety which does not grow more than a foot high: the leaves smooth, growing by threes, narrower and shorter than the common sort: the flowers in terminating spikes, of a light purple colour, appearing in July. Likewise, in which the stalks are slender, not more than nine or ten inches long, spreading out on every side: the lower part has oblong-ovate leaves, placed opposite: on the upper part the leaves are narrower and alternate: the flowers come out singly from the side of the stalks at each joint; they are larger than those of the common sort, and of a deeper purple colour; making a fine appearance in July, when they are in full beauty and perfection.

Culture.—This sort and varieties may be readily increased by parting the roots in autumn, and planting them out in the situations where they are to remain. They may likewise be raised from seed sown at the same time; but the first is the readiest method.

They delight in a rather moist soil.

All of them are highly ornamental in the larger borders, clumps, and other parts of pleasure-grounds, being placed towards the back parts.

MADWORT. See ALYSSUM.

MAGNOLIA, a genus containing plants of the evergreen and deciduous tree kinds.

It belongs to the class and order *Polyandria Polygynia*, and ranks in the natural order of *Coadunatæ*.

The characters are: that the calyx is a three-leaved perianthium: leaflets ovate, concave, petal-shaped, deciduous: the corolla has nine oblong petals, concave, blunt, narrower at the base: the stamina have numerous filaments, short, acuminate, compressed, inserted into the common receptacle of the pistils below the germs: anthers linear, fastened on each side to the margin of the filaments: the pistillum has numerous germs, ovate-oblong, two-celled, covering a club-shaped receptacle: styles recurved, contorted, very short: stigmas longitudinal of the style, villose: the pericarpium is an ovate strobile, covered with capsules, which are compressed, roundish, scarcely imbricate, clustered, acute, one-celled, two-valved, sessile, opening outwards, permanent: the seeds two or one, roundish, berried, hanging by a thread from the sinus of each scale of the strobile.

The species cultivated are: 1. *M. grandiflora*, Laurel-leaved Magnolia; 2. *M. glauca*, Swamp Deciduous Magnolia; 3. *M. acuminata*, Blue Magnolia; 4. *M. tripetala*, Umbrella Magnolia, or Umbrella Tree.

The first rises with a straight trunk of two feet or more in diameter to the height of seventy or eighty feet, or more, dividing into many spreading branches, that form a large regular head: the leaves are nine or ten inches long, and three inches broad in the middle, of a thick consistence, resembling those of the common laurel, but much larger, entire, but a little waved on their edges, of a lucid green on the upper surface, and sometimes russet-coloured underneath; they are sessile, placed without order on every side the branches, and continue green throughout the year, falling off only as the branches extend, and new leaves are produced: the flowers are produced at the ends of the branches; are very large, and are composed of eight or ten petals, narrow at their base, but broad, rounded, and a little waved at their extremities; they spread open very wide, are of a pure white colour, having an agreeable

scent. In its native country it begins to produce flowers in May, and continues a long time in flower, so that the woods are perfumed with their odour the greatest part of the summer: but in this climate it seldom begins to flower till the middle or end of June, and does not continue long in beauty. It is a native of Florida and Carolina.

It varies with broad leaves, and with narrow leaves.

The second species grows about fifteen or sixteen feet high, with a slender stem, covered with a smooth whitish bark: the wood is white and spongy: the leaves thick and smooth, resembling those of the bay, entire, dark green on their upper surface, but whitish or glaucous and a little hairy underneath: the flowers are produced in May and June at the extremity of the branches; are white, and have an agreeable sweet scent, with only six concave petals: after these are past the fruit increases to the size of a walnut, with its cover an inch or more in length, and three-fourths of an inch in diameter, of a conical shape: the seed is about the size of a kidney-bean: this fruit is at first green, afterwards red, and when ripe of a brown colour. Where it grows naturally, there is a succession of flowers on the trees for two months or more: but in this climate there are seldom more than twelve or fourteen flowers on a tree, and those of short duration. It is a native of North America.

The young plants often retain their leaves through the greatest part of winter; but, when three or four years old, constantly cast their leaves by the beginning of November.

There is a variety with long leaves, which is evergreen.

The third grows sometimes to the height of thirty or forty feet, in its native state, and the trunk is eighteen inches or more in diameter: the leaves near eight inches long, and five broad: the flowers come out early in the spring, are composed of twelve large blueish-coloured petals: the fruit is about three inches long, somewhat resembling a small cucumber; whence the inhabitants of North America call it Cucumber Tree: the wood is of a fine grain, and an orange colour. It is a native of North America.

The fourth species grows from sixteen to twenty feet high, with a slender trunk, covered with a smooth bark, and dividing into several branches: the leaves are remarkably large, often from twelve to fifteen inches or more in

length, and five or six in width, narrowing to a point at each extremity, placed at the ends of the branches in a circular manner, somewhat like an umbrella, whence its name: the flowers are composed of ten, eleven, or twelve large, oblong, white petals; the outer ones hanging down: the seed-vessels are oblong, conical, between three and four inches in length, and about an inch and half in diameter. The wood is soft and spongy; and the leaves drop off at the beginning of winter. It is a native of Carolina, Virginia, &c.

Culture.—These plants may all be increased by seed, layers, and cuttings.

In the first mode, the seed, which is received annually from America, preserved in sand, early in the spring, should be sown as soon after as possible in pots of light rich earth, half an inch deep, plunging them in a moderate hot-bed, to bring up the plants an inch or two in height, or in the common earth under a warm wall or hedge, or in a frame, in the full sun, till the middle or latter end of April, then replunging them in an easterly border open to the morning sun; giving moderate sprinklings of water in dry weather. The plants will rise the same year; those in the hot-bed, probably in April, and the others in May, inuring those in the first situation timely to the full air. The plants should all summer be regularly supplied with water, and at the approach of winter be removed into a green-house, or rather under a garden-frame, to be sheltered from frost all winter, indulging them with the open air in mild weather. If the pots be plunged in a bark hot-bed, &c. about March, under a frame, two or three months, it will forward the plants greatly; being careful to give water, and harden them to the open air gradually, so as to be removed into it in their pots fully in June, to remain till the autumn, when they should be allowed shelter in winter, as before. The spring following, they should be planted into separate pots, and plunged into a hot-bed as before to set them forward, giving water, occasional shade, and the benefit of free air; and in June removing the pots to a shady border for the remainder of the summer. In winter they should have shelter as before, from severe frost, but have the full air in all open weather. They require the same care for two or three winters, when some of them may be turned out of the pots with balls of earth about their roots, into the full ground, in a warm sheltered situation, particularly the deciduous kinds; but the first or evergreen sort should not be too soon exposed to the winter's cold, but be continued in occasional shelter in the above manner four or five years, till two, three, or more feet high;

and when turned out, matted occasionally in severe winters, retaining some in pots to be managed as green-house plants of the more hardy kind.

The layers should be laid down in autumn or spring, choosing the young pliable shoots for the purpose, giving them a gentle twist, or a slit in the part laid into the earth. Some will be well rooted in one year, others probably not in less than two; then take them off, and plant each in a pot in the early spring, plunging them in a moderate hot-bed for a month or two, to promote their growing freely at first, and they will form good strong plants by the following autumn, allowing them shelter in winter for a year or two, when they may be planted out.

The cuttings should be made from the short young shoots of the preceding year, and be planted in pots of good earth, plunging them to the rims in the common or stove hot-bed, giving water and occasional shade; some of them will be rooted the same year, when they must be inured by degrees to the open air, after which they may be managed as the layers.

The first or evergreen sort is one of the most beautiful trees in nature, both in its growth, and in the luxuriance of its noble leaves, which render it singularly conspicuous at all seasons.

The deciduous sorts are also highly ornamental trees, and may be introduced into clumps and shrubberies, where by their fine foliage they exhibit an elegant variety.

All the different species are cultivated in the nurseries, for sale, from which they may be taken up and planted out in the early spring or autumn months; but the former is the better.

In their disposition in the shrubbery, as they are rather tender in their early growth, they should have a sheltered sunny situation, in a rather dry soil, being planted in the most conspicuous places, and not too closely crowded with other shrubs.

They have also a good effect when disposed singly in different parts, in open spaces of short grass-ground, in sheltered situations; especially the first sort.

MAHERNIA, a genus containing plants of the shrubby exotic kind, for the green-house.

It belongs to the class and order *Pentandria Pentagynia*, and ranks in the natural order of *Columniferae*.

The characters are: that the calyx is a one-leaved perianthium, five-cleft, bell-shaped; with awl-shaped longer teeth; permanent: the corolla has five heart-shaped petals, oblong, spreading, twice as long as the calyx: nectaries five,

obcordate, pedicelled, surrounding the germ, shorter than the calyx: the stamina have five filaments, capillary, placed on the nectary, united at the base, shorter than the calyx: anthers oblong, acuminate, erect: the pistillum is a sub-pedicelled germ, obovate, five-angled: styles five, bristle-shaped, erect, the length of the petals: stigmas simple: the pericarpium is an ovate capsule, five-celled, five-valved: the seeds few, and kidney-form.

The species cultivated are: 1. *M. pinnata*, Wing-leaved Mahernia; 2. *M. incisa*, Cut-leaved Mahernia.

The first rises with a shrubby stem near three feet high, sending out many slender delicate branches, covered with a reddish bark: the flowers come out from the side of the branches in small clusters, are of a lively red when they first open, and hang down like little bells, commonly two together; appearing from June to August and September. It is a native of the Cape.

In the second species, the stalks to the naked eye discover a manifest roughness; with a magnifying glass, it appears that they are beset on every side with little protuberances, whence issue tufts of pellucid hairs, and here and there a single hair is discoverable with a small red viscid globule at its extremity: a portion of the stalk, when highly magnified, somewhat resembles that of the creeping *Cereus*: the leaves, which are not so manifestly hairy as the stalk and calyxes, are deeply jagged on the edges, and somewhat resemble those of *Pelargonium Tricolor*: the flowers when in bud are of the richest crimson: as they open they incline to a deep orange, and finally become yellowish. It is a native of the Cape.

Culture.—These plants may be increased by planting cuttings of the young branches in the summer season singly, in pots of light mould, watering them, and plunging them in a hot-bed till they have stricken root. When they have become well rooted, they may be removed into the green-house for protection during the winter season; being managed as the less tender plants of this sort.

They afford variety among other potted plants of a similar kind.

MAHOGANY TREE. See SWIETENIA.

MALLOW, INDIAN. See SIDA.

MALLOW TREE. See LAVATERA.

MALLOW, VENICE. See HIBISCUS.

MALOPE, a genus containing a plant of the herbaceous kind.

It belongs to the class and order *Monadelphiu Polyanthia*, and ranks in the natural order of *Columniferae*.

The characters are: that the calyx is a double perianthium: outer three-leaved, broader: leaflets cordate, acute, permanent: inner one-leaved, half-five-cleft, more erect, permanent: the corolla has five obcordate petals, præmorse, spreading, fastened to the tube of the stamina at the base: the stamina have numerous filaments, at bottom united into a tube, above, at, and below the apex of the tube, separate and loose: anthers almost kidney-form: the pistillum has roundish germs: style simple, the length of the stamina: stigmas many, simple, bristle-shaped: the pericarpium is a roundish capsule, many-celled: cells as many as there are stigmas, conglomerated into a head: the seeds solitary and kidney-form.

The species cultivated is *M. Malacoides*, Betony-leaved Malope.

In the whole plant it has greatly the appearance of the mallow, but differs from it in having the cells collected into a button, somewhat like a blackberry: the branches spread, and lie almost flat upon the ground, extending a foot or more each way: the flowers are produced singly upon long axillary peduncles, and are in shape and colour like those of the mallow. It is a native of Tuscany, &c.

Culture.—This may be increased by sowing the seeds, in the places where the plants are designed to remain, as it does not bear transplanting well: when they are sown upon a warm border in August, the plants also frequently stand through the winter, and flower early the following season, so as to produce good seeds: but when sown in the spring, this is rarely the case.

The plants sown in the spring in pots should be protected in winter under a frame. They seldom continue longer than two or three years.

They afford variety among other plants in the borders, &c.

MALPIGHIA, a genus containing plants of the exotic evergreen shrubby kind, for the stove.

It belongs to the class and order *Decandria Trigynia*, and ranks in the natural order of *Trifoliatae*.

The characters are: that the calyx is a five-leaved erect perianthium, very small, permanent, converging: there are two melliferous glands, oval and gibbous, fastened to the calyxine leaflets on the outside and at bottom: the corolla has five petals, kidney-form, large,

plaited, ciliate, spreading, concave; with long linear claws: the stamina have ten broadish filaments, awl-shaped, erect, placed in a cylinder, united below, small: anthers cordate: the pistillum is a roundish germ, very small: styles three, filiform: stigmas blunt: the pericarpium is a globular berry, torulose, large, one-celled: the seeds three, bony, oblong, blunt, angular; with an oblong blunt kernel.

The species cultivated are: 1. *M. glabra*, Smooth-leaved Barbadoes Cherry; 2. *M. punicifolia*, Pomegranate-leaved Barbadoes Cherry; 3. *M. urens*, Stinging Barbadoes Cherry; 4. *M. nitida*, Shining-leaved Barbadoes Cherry; 5. *M. angustifolia*, Narrow-leaved Barbadoes Cherry; 6. *M. crassifolia*, Thick-leaved Barbadoes Cherry; 7. *M. verbascifolia*, Mullein-leaved Barbadoes Cherry; 8. *M. coccigera*, Scarlet Grain-bearing Barbadoes Cherry.

The first grows to the height of fifteen, sixteen, or eighteen feet, with several trunks, covered with a clay-coloured smooth bark, and dividing into many spreading branches, making a pleasant round head: the leaves are opposite, subsessile, acute, continuing all the year: the flowers are in axillary and terminating bunches, or umbels, on peduncles half an inch long, and about four flowers on each, of a bright purple: the pedicels have a single joint: the fruit red, round, the size of a cherry, smooth-skinned, having one or more furrows on the outside, and containing within a reddish, sweetish, not unpleasant, copious, juicy pulp.

It is found in the West-Indies, flowering from December to March.

The second species rises with a shrubby stalk from seven to ten or twelve feet high, dividing into several slender spreading branches, covered with a light brown bark: the flowers are produced in small umbels at the end of the branches, upon short peduncles: the corolla is pale rose-colour: the berry roundish, pulpy, with several furrows, red when ripe, inclosing three or four hard angular seeds. It is of the same size and make with our common cherries, very succulent, and of a pleasant subacid taste; having much the appearance of the pomegranate. It is a native of the West-Indies.

The third is a shrub, which rises with a strong upright stem about three feet high, covered with a brown bark, sending out several side branches which grow erect: the leaves ending in acute points, sessile, covered with fine bristles, which do not appear unless closely viewed: these bristles are double-pointed, and sustained by pedicels of the same fragile transparent substance with themselves, descending from the

middle of them: these are easily broken, but the bristles enter pretty deep in, and stick close to whatever has forced them off. The flowers come out upon long slender peduncles from the axils at each joint, four, five, or six together, in a sort of whorl. It flowers in July and August, (to October), and is found in the West-Indies.

The fourth species is a shrub, a fathom in height: the stem upright, round, even: the branches decussated, upright, round, covered with a shining bark: the leaves decussated opposite, oblong, blunt, with a convex margin, nerved, veined, firm, pale-green, shining, on short petioles: the racemes axillary, shorter than the leaves, many-flowered: the flowers peduncled, the same size as in the first sort, yellow: the berry three-lobed, three-seeded, and blood-red. It is a native of the West-Indies.

The fifth rises with a shrubby stalk seven or eight feet high, covered with a bright purplish bark, which is spotted and furrowed, dividing towards the top into several smaller branches: the leaves are numerous, about two inches long, and a quarter of an inch broad, acuminate, of a lucid green on their upper side, but of a russet brown on their under, where they are closely armed with stinging bristles: the flowers are from the side and at the end of the branches in small umbels, small, and of a pale-purple colour: the fruit small, oval, furrowed, and dark purple when ripe. It is a native of the West-Indies, flowering in June.

The sixth species is a tree, with the leaves a hand in length, thick, subpetioled, quite entire, pubescent above, tomentose underneath, commonly alternate: the racemes long, tomentose; and according to Brown, the upper branches terminate in loose bunches of flowers, each of the divisions being simple, as well as the top of the main supporter, which terminates also in a single spike. It is a native of the West-India islands.

The seventh has the leaves ending in the petioles, a foot long, villous, clothed underneath with a very close nap: the racemes long and villous. It is a native of South America.

The eighth species is a very low shrub, seldom rising more than two or three feet high: the stalk thick and woody, as are also the branches, which come out on every side from the root upwards, and are covered with a rough gray bark: the leaves lucid, half an inch long, and almost as much broad, appearing as if cut at their ends, where they

are hollowed in, and the two corners rise like horns, ending in a sharp thorn, as do also the indentures on the sides: the flowers come out from the side of the branches, upon peduncles an inch long, each sustaining one small pale bluish flower: the fruit is small, conical, furrowed, changing to a purple red colour when ripe. It is found in the West-Indies.

Culture.—These plants may be increased by sowing the seeds in the spring, in pots of light rich earth, and plunging them in a hot-bed. When the plants have attained a few inches in growth they should be planted out into separate small pots, re-plunging them in a bark hot-bed in the stove, where they should remain, the two first winters, being afterwards placed in a dry stove, and kept in a moderate warmth, water being occasionally given in small quantities.

They afford ornament among collections of plants of similar kinds.

MALVA, a genus containing plants of the herbaceous, annual, biennial, perennial, and shrubby kinds.

It belongs to the class and order *Monadelphia Poljandria*, and ranks in the natural order of *Columniferae*.

The characters are: that the calyx is a double perianthium: outer three-leaved, narrower: leaflets cordate, acute, permanent: inner one-leaved, half-five-cleft, larger, broader, permanent: the corolla has five obcordate petals, præmorse, flat, fixed to the tube of the stamens at the base: the stamina have numerous filaments, united below into a tube, seceding and loose at the top and surface of it: anthers kidney-form: the pistillum is an orbicular germ: style cylindric, short: stigmas very many, bristly, the length of the style: the pericarpium is a roundish capsule, composed of very many cells, (as many as there are stigmas,) two-valved, placed in a whorl about a columnar receptacle, finally falling: the seeds are solitary, very seldom two or three, kidney-form.

The species cultivated are: 1. *M. spicata*, Spiked Mallow; 2. *M. Americana*, American Mallow; 3. *M. Peruviana*, Peruvian Mallow; 4. *M. Caroliniana*, Creeping Mallow; 5. *M. Orientalis*, Oriental Mallow; 6. *M. verticillata*, Whorl-flowered Mallow; 7. *M. crispa*, Curled Mallow; 8. *M. Ægyptia*, Palmated Mallow; 9. *M. Alcea*, Vervain Mallow; 10. *M. moschata*, Musk Mallow; 11. *M. Capensis*, Gooseberry-leaved or Cape Mallow.

The first has the stem pale-green, two or three feet high, and branched: the leaves are almost round, an inch and quarter long, and three

quarters of an inch broad at the base, pale-green, smooth, on petioles three quarters of an inch in length: the tops of the twigs and branches, for the length of an inch, are thick set, in a spike with orange-coloured flowers, in very hirsute calyxes. It is a native of Jamaica, flowering in September and October.

The second has an annual root: the stem is a foot high, stiff, round, somewhat hairy: branches few, short, upright, from the lower axils: the leaves scarcely tomentose: peduncles axillary, upright, solitary, one-flowered: the spike terminating, with many sessile flowers, expanding after noon: the corolla yellow. It is a native of North America, flowering in June and July.

The third is also an annual plant: the stem from two to three feet high, with hairs thinly scattered over it, usually in pairs: the leaves seven-lobed, (five or three) plaited, smooth, veined, sharply serrate, on petioles the length of the leaf: the stipules ovate-lanceolate: the peduncles long, naked: the spike directed to one side, turned upwards, recurved before the flowers open: the corollas small, purple. According to Jacquin, the flowers are red: but others say, pale blue, and set very closely on the spikes, appearing in June. It grows naturally in Peru.

The fourth has an annual root: the stems creeping, eighteen inches and longer, round, putting out roots at the lower joints, hairy: the leaves villose, soft; those next the root large, roundish, gash-serrate, smaller and more deeply divided as they ascend, five-lobed and seven-lobed, all on long hairy petioles, gashed and serrate on the edge: the flowers are axillary and terminating, on almost upright peduncles, from an inch to an inch and half in length, small, the colour of Burgundy wine: the claws of a darker red. It is a native of Carolina.

The fifth species is an annual plant, with an upright stalk: the flowers are large, and of a soft red-colour. According to Martyn, the stalk is six feet or more in height, and the flowers not purple, but dark red, with the veins so dark as to be almost black. It was found in the Levant.

The sixth has the root annual, three feet high: the leaves cordate, five- or seven-angled, subcrenate, smooth, on long alternate petioles: the flowers are whitish red, small, on one-flowered peduncles. It is a native of China, and Cochinchina, flowering in June and July.

The seventh species is also annual: the stem upright, four or five feet high: the leaves curled on their edges: the stem thick, round, green, hirsute below, branched, from three to four

feet high: the lower leaves a hand wide, on long petioles; the upper ones smaller, on shorter petioles; the uppermost very small, almost sessile: all obscurely angular, sinuate, bright green, pubescent: the flowers sessile in the axils, over the whole stem and branches, small in proportion to so large a plant. It is a native of Syria, flowering from June to August.

The eighth is likewise an annual plant, with stalks about a foot long, smooth, and declining: the leaves on pretty long footstalks: the flowers single from the axils, and at the top in clusters: the calyxes large, acute: the corollas small, pale blue. It is a native of Egypt, flowering in June and July.

The ninth has the root long, branched, and perennial: the stem from two to three feet high, round, rugged, hairy: hairs in bundles, spreading: branches alternate: the leaves alternate, semiorbicular, five-parted to the base, with the lobes oblong, three- or five-parted, bright green, whitish underneath, pubescent, somewhat rugged: the petioles round, with very small awl-shaped stipules at the base: the flowers terminating in panicles or bundles: the calyx small in proportion to the size of the corolla, pubescent; outer small, inner much larger: the corolla an inch and half or two inches long, five-parted to the base, bright purple; with blunt two-lobed segments. It is a native of many parts of Europe.

The tenth species has root-leaves roundish, kidney shaped, entire, except being crenate on the margin: the first stem-leaves three-lobed, divided half way down: side-lobes divided again into two or three, but not so deeply: above these they are three-lobed to the footstalk: lobes again deeply divided; divisions deeply jagged: higher ones five-lobed, lobes pinnatifid, segments of the upper ones more divided, and narrower; uppermost linear: the stem round, much branched, slightly hairy: at the origin of each branch, two lanceolate hairy stipules: the flowers crowded on the top of the stem and branches on short peduncles, and single ones from the axils of the upper leaves: petals heart-shaped, divided nearly to the base, pale red or flesh-coloured, with deeper veins. It differs from the ninth sort, with which it has been confounded, in having the stem not so tall, with solitary upright hairs rising from a prominent little point: the arils rough with hairs: the flowers of an ambrosial or musky scent: the musky smell is not however always to be perceived. Mr. Curtis, on cultivating both species together, found the ninth grow nearly to twice the height of this,

and to be in every respect a stronger plant, and harsher to the touch. It is a native of many parts of Europe.

The eleventh rises with a woody stalk ten or twelve feet high, sending out branches from the side, the whole length: the stalks and branches are closely covered with hairs: the leaves are hairy, indented, on their sides, so as to have the appearance of a trilobate leaf: those on the young plants are three inches long and two broad at their base: but as the plants grow older, they are scarcely half that size: the flowers come out from the side of the branches, upon peduncles an inch long; they are of a deep red colour, shaped like those of the common mallow, but smaller. It flowers great part of the year, and is a native of the Cape.

There are varieties in which the stems are thicker and higher, of a brownish red colour: the leaves hirsute, broader, with wider segments, less deeply cut, but with the toothlets sharper and serrate: the whorls of fruit a little larger, and not mucicated; and in which the hairs of the leaves and stem are simple, not compound: the flowers almost upright, not drooping.

Culture.—The ten first sorts are all capable of being raised from seeds, which, in the hardy kinds, should be sown in the situations where the plants are to grow, in patches of four or five in each, in the spring or beginning of autumn, covering them to the depth of half an inch. They may likewise be sown upon a bed of fine earth, and be afterwards removed to the places where they are to flower. Those which are natives of hot climates, should be sown in pots and plunged in a hot bed.

When the plants in the two latter modes have attained some growth, they should be removed into their proper situations, or into other pots, to be afterwards managed according to the difference of the kinds.

The last sort and varieties may be raised also by seed, which should be sown upon a hot-bed, or in pots and plunged in it. When the plants have attained some growth, they should be removed into separate pots, replunging them in the hot-bed till fresh rooted, when they should be gradually inured to the full air, managing them afterwards in the same manner as other exotics of the green-house kind.

The hardy sorts afford a pleasing variety in the shrubbery and other parts, while those of the more tender and shrubby kind produce a good effect in the green-house, and among potted collections.

MANMEA, a genus containing plants of the evergreen exotic tree kind.

It ranks in the class and order *Polygamia*

Monoclin, or *Dioclin*, and ranks in the natural order of *Guttiferae*.

The characters are: that in the hermaphrodite, the calyx is a one-leafed perianthium, two-parted: divisions roundish, concave, coriaceous, coloured, spreading very much, deciduous: the corolla has four roundish petals, concave, spreading very much, subcoriaceous, longer than the calyx: the stamina have numerous bristle-shaped erect filaments, very short, inserted into the receptacle, ending in oblong, blunt, erect anthers: the pistillum is a roundish, depressed germ: style cylindric, erect, longer than the stamens, permanent: stigma capitate, convex: the pericarpium is a roundish fleshy berry, very large, acuminate with part of the style, with a coriaceous rind, one-celled: the seeds four, subovate, rugged, distinct from the flesh: male on the same or a different tree: the calyx, corolla, and stamina, as in the hermaphrodite.

The species is *M. Americana*, American Mammee.

It is a tall upright handsome tree, with a thick spreading elegant head, and a long down-right tap-root, which renders it very difficult to transplant: the younger branchlets are quadrangular: the leaves oval or obovate, quite entire, blunt, extremely shining, leathery, firm, with parallel transverse streaks, on short petioles, opposite, from five to eight inches in length: the peduncles one-flowered, short, scattered over the stouter branches: the flowers are sweet, white, an inch and half in diameter: the fruit roundish, or obsoletely three-cornered or four-cornered according to the number of seeds, one or two of which are frequently abortive, varying in size from three to seven inches in diameter, being covered with a double rind: the outer leathery, a line in thickness, tough, brownish yellow, divided by incisures longitudinally decussated; the inner thin, yellow, adhering strongly to the flesh; which is firm, bright yellow, has a pleasant singular taste, and a sweet aromatic smell; but the skin and seeds are very bitter and resinous. It is eaten raw alone, or cut in slices with wine and sugar, or preserved in sugar. It is a native of the Caribbee islands.

Culture.—These trees may be raised from seeds procured from America, which should be sown in the early spring, in pots filled with light fresh mould, plunging them in a bark hot-bed, keeping the mould moist by occasional watering, when they will soon come up. The young plants should be often watered in dry weather. When they have attained some growth, they should be removed with earth

VOL. II.

about them, into other pots a little larger, being replunged in the hot-bed till fresh rooted, filling up the pots with fresh mould; due shade, air, and water being given. In the autumn they should be removed into the stove, where they must be kept, being shifted into other pots in the following spring; having regard not to over-pot them.

They may also be raised by placing the stones of the fruit under the pots upon the tan, more expeditiously than when planted in the mould of the pots.

They afford a fine variety among other stove plants.

MANGA. See **MANGIFERA**.

MANGIFERA, a genus containing a plant of the tree exotic kind for the stove.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Terebinthaceae*.

The characters are: that the calyx is a five-parted perianthium: divisions lanceolate: the corolla has five lanceolate petals, longer than the calyx: the stamina have five awl-shaped filaments, spreading, the length of the corolla: anthers subcordate: the pistillum is a roundish germ: style filiform, the length of the calyx: stigma simple: the pericarpium is a kidney-form drupe, oblong, gibbous, compressed: the seed is a kernel, oblong, compressed, lanuginose.

The species cultivated is *M. Indica*, Mango-tree.

It is a large spreading tree in its native state: the wood is brittle, brown, and used only for indifferent works: the bark becomes rugged by age: the leaves are seven or eight inches long, and two or more broad, lanceolate, quite entire, smooth, of a fine shining green, and a sweet resinous smell, terminating in points, and having several transverse parallel opposite ribs; they are on short petioles, and grow in bunches at the extremity of the branches. The flowers are produced in loose bunches at the end of the branches. The fruit, when fully ripe, is yellow and reddish, replete with a fine agreeable juice, being sometimes as big as a large man's fist. It grows naturally in most parts of India, &c.

There are several uncultivated varieties.

Culture.—As the vegetative property of the seed or nuts of this species does not seem to be long preserved, the readiest method to obtain plants, is to have a quantity of the nuts set in tubs of earth in the country where they grow naturally, and when the plants are grown a foot high, to have them shipped, placing a covering over them to defend them from the water and spray of the sea, being careful not to give them too

N

much water in the passage. When they arrive in a cold climate, they should be screened from cold. The plants should afterwards be set in pots filled with light kitchen-garden earth, and be placed in a dry stove, where, in warm weather, they should have fresh air daily, and in winter the air be kept up to temperate, as marked on the botanical thermometer; as they do not succeed well in the tan-bed.

Where the nuts are made use of, they should be sent over in wax to preserve their vegetative property.

They may also be increased from cuttings, in the manner of *Gardenia*, in this climate.

MANGO-TREE. See *MANGIPERA*.

MANGROVE GRAPE-TREE. See *Coccoloba*.

MANNA ASH. See *FRAXINUS*.

MANURE, such substances or materials, whether of the dung, compost, or other kinds, as are useful in the improvement of land, so as to produce good vegetable crops.

Materials of this kind are necessary to all soils, to repair them when exhausted by the growth of vegetables, and cure their defects; being thus beneficial in enriching and fertilizing such as are poor, and in rendering such as are strong or stubborn more light, loose, and friable, as well as those which are very light, loose, and dry, more compact and moist, and those that are too wet drier, &c. In this view, moist stiff land is the most improved by light Manures, which open and loosen its particles; very light land by the more heavy and moist sorts; and wet land by dry light composts. Some soils also require Manure annually, while others only once in two or three years. See *DUNG*, &c.

The most proper sorts of Manure for the use of the kitchen-garden are those of the stable, cow, sheep, and pigeon dung, soot, lime, loamy marle, shell marle, sea-weed, wood, whin, fern, and coal ashes, the vegetable mould of decayed tree-leaves, and decayed vegetables of all kinds, as cabbage leaves, haulm, weeds, &c. And to these may be added the fluid substance which drains from dunghills, which is capable of affording the nutrition of plants in a very high degree, from the large proportion of carbonaceous matter that it contains.

These materials may be applied either in a simple or compound state; but the latter method is probably in general the most eligible; as it is supposed by some, that if they have not undergone a proper degree of fermentation, they have the effect of giving a rank and disagreeable flavour to some fruits and vegetables; and when a large quantity is applied, of producing a considerable degree of unwholesome-

ness, tainting the juices of the plants. This effect is, however, much to be disputed, since the different substances are changed and elaborated in the vessels of the vegetables before they become fit for the purpose of their increase.

The author of the *Scotch Forcing Gardener* asserts that "a combination of stable dung, sea weed, lime, and vegetable mould, which has lain in a heap for three or four months, and has been two or three times turned during that period, will make an excellent Manure for most kinds of garden land." Also that of "cow dung and sheep dung, mixed with soot or any of the kinds of ashes;" and that "pigeon dung, marle, and vegetable mould, well mixed, will make an excellent Manure for heavy land; or even for lighter soils, provided the pigeon dung be used sparingly." But that "pigeon dung, lime, soot, ashes, &c., should never be applied in a simple state: the quantity of them required being comparatively small, and the regular distribution difficult without the admixture of other matter. He further observes, that he has "witnessed the astonishing effects of whin ashes alone, in producing herbage in a five or six fold degree; which was the more obvious, on account that the field on which they were applied was much alike in quality (a stiff, wet, clayey loam), and the ashes applied partially. The effect was visible for several successive years. Also, on the timber trees with which the field was afterwards planted." He conceives that "marle is an excellent Manure for almost any soil; and may be applied as a simple with as much propriety as any of the kinds of cattle dung, or even vegetable earth. The kind called shell marle is, he thinks, much to be preferred; and should be freely applied to strong lands, but sparingly to light: the loamy kind being best adapted to light lands."

When stable dung is used in a simple state, it "should not," he supposes, "be applied in too rank a state, nor should it be too much fermented. It should generally lie in a heap for two or three months; during which time it should be turned twice or thrice. A ton of it in this state is worth three that has been used in the hot-bed, and is a year old. This Manure, and indeed dung of any kind, when thus applied, should never be carried from the heap to the ground till it is to be dugged in; as, by its exposure to the air, the virtues evaporate, and it is the less effectual."

And when made use of in a simple condition, he imagines "the necessity of the instant application of sea weed after its landing, is even greater than the above case; as it instantly

corrupts, and its juices not only evaporate, but flow downwards, and are lost. If this Manure is used as a compound, the heap wherein it is compounded should be more frequently turned on its account, that none of the juices may be lost, but that the other part of the compost may absorb them."

In his opinion "vegetable mould may either be used in a simple or compound state, and may be applied with equal propriety to all soils. None can," says he, "be hurt by it in any degree; since almost every plant will grow luxuriantly in it entirely, without the aid of any soil or manure whatever." He considers Manures as having the effect of correcting tenacity, crudity, and porosity in soils, exciting their fermentation, communicating nutritive matter, and affording nourishment to the roots of plants, by which the vegetation and perfect growth of plants is promoted.

There are considerable differences in the materials made use of as Manures, in their affording their nutritious properties, some affording them much more readily and more abundantly than others. This is the case with animal, vegetable, and all such matters as are rich in mucilage, the saccharine principle, and calcareous earth, and which readily afford carbon, phosphorus, and some gaseous fluids, such as the carbonic acid gas, oxygen, &c. while others which are greatly deficient in all or most of these principles, or which do not part with them easily, are found by experience much less beneficial in promoting the growth of vegetables.

As the effects and importance of Manure are now generally acknowledged and understood, it would appear to be the indispensable duty of the gardener and cultivator to be particularly careful in the collection of it, and also to distribute it with the most skillful frugality. "For this purpose, it is suggested that a well, cistern, &c. should be contrived so as to collect the dunghill drainings; and that in the application of Manure of any kind, the greatest care should be taken to divide it equally, according to the quantity to be applied." And further, that "the dunghill may be considerably increased by throwing the haulm, stalks, and leaves of all vegetables into a common heap, letting them remain till well rotted, and afterwards, or in the process of collection, mixing them with lime, marle, ashes, soot, &c. Watering the whole frequently with the drainings of the dunghill, would also greatly enhance its value."

The ground of gardens may often be greatly ameliorated and improved by proper draining, before the manures are applied, and sometimes by the use of sandy, gravelly, and other similar

materials, that have the power of opening, and rendering it less close and adhesive.

MARANTA, a genus containing plants of the herbaceous perennial exotic kind.

It belongs to the class and order *Monandria Monogynia*, and ranks in the natural order of *Scitamineæ*.

The characters are: that the calyx is a three-leaved perianthium, lanceolate, small, superior: the corolla is one-petalled, ringent: tube oblong, compressed, oblique, bent in: border six-cleft: alternate outer segments ovate, equal, smaller; one of these the lowest, two the uppermost: two alternate, lateral, very large, roundish, representing the lower lip: uppermost small, two-parted: the stamina have membranaceous filaments, resembling a segment of the corolla: anthers linear, fastened to one edge of the filament: the pistillum is a roundish inferior germ: style simple, the length of the corolla: stigma obsoletely three-cornered, bent in: the pericarpium is a roundish capsule, obsoletely three-cornered, three-celled, three-valved: the seed single, ovate, wrinkled, and hard.

The species cultivated is *M. arundinacea*, Indian Arrow-root.

It has a thick, fleshy, creeping root, which is very full of knots, from which arise many smooth leaves, six or seven inches long, and three broad towards their base, lessening towards each end, terminating in points: they are of the consistence and colour of those of the reed, and stand upon reed-like foot-stalks, which arise immediately from the root: between these come out the stalks, which rise near two feet high; these divide upward into two or three smaller, and have at each joint one leaf of the same shape with the lower, but smaller: the ends of the stalks are terminated by a loose bunch of small white flowers, standing upon peduncles near two inches long: the flowers are cut into six narrow segments, which are indented on their edges; these sit upon the embryo, which afterwards turns to a roundish three-cornered capsule, inclosing one hard rough seed. It is a native of South America, flowering in June and July, in this climate.

The root washed, pounded fine, and bleached, makes a fine nutritive powder, which is made use of as food.

Culture.—These plants may be increased by dividing the roots and planting them in pots of light rich earth, in the spring, just before they begin to shoot, plunging them in the bark hot-bed of the stove, where they must be kept in general, being frequently refreshed with water, when in a state of growth, having free air, after they become of some strength.

They afford ornament and variety in stove collections.

• **MARIGOLD.** See *CALTHA*.

• **MARJORAM.** See *ORIGANUM*.

MARLE, a sort of fossile earthy substance, made use of for rendering stiff adhesive garden-lands more open and light.

It varies much in its nature, some being nearly of the nature of fuller's earth, and of a fat enriching quality, of which there are blue, gray, yellow, and red coloured; but the blue is esteemed the best. In other cases, it has the appearance of a kind of soft stone, or rather slate, of a blueish or gray colour, called stone or slate marle, being found commonly near river-sides, and the sides of hills, &c. and though hard when dug, easily dissolves by rain and frost. There are likewise calcareous, or shell and claymarles, the latter resembling a fat sort of clay or loam. The last sort is accounted good manure for improving light, loose, sandy, garden lands. See **MANURE**.

MARRUBIUM, a genus containing plants of the shrubby kind.

It belongs to the class and order *Didynamia Gymnospermia*, and ranks in the natural order of *Verticillatae*.

The characters are: that the calyx is a one-leaved, salver-shaped perianthium, rigid, ten-streaked; mouth equal, patulous, often ten-toothed; toothlets alternate, smaller: the corolla one-petalled, ringent; tube cylindrical: border gaping, with a long tubular opening: upper lip erect, linear, bifid, acute: lower reflex, broader, half-three-cleft; the middle segment broader, emarginate, the lateral ones acute; the stamina have four filaments, shorter than the corolla, concealed beneath the upper-lip, two longer; anthers simple: the pistillum is a four-cleft germ: style filiform, of the same length and in the same situation with the stamens: stigma bifid: there is no pericarpium: calyx contracted at the neck, spread out at the mouth, inclosing the seeds: the seeds four, somewhat oblong.

The species cultivated are: 1. *M. Pseudo-Dictamnus*, Shrubby White Horehound; 2. *M. acetabulosum*, Saucer-leaved White Horehound.

The first rises with a shrubby stalk two feet high, dividing into many branches: the leaves are small, sitting pretty close to the stalks: the whorls of flowers not so large as those of the eighth sort: the rim of the calyx flat: the flowers white: the whole plant very hoary with a dense compact cotton. It is a native of the island of Candia, flowering from June to August.

The second species has the stems hairy, about

two feet high: the leaves heart-shaped, rough on their upper side, and hoary on their under, deeply serrate: the whorls large: the border of the calyx flat; segments many, membranaceous, angular, and rounded at the top: the corolla small, pale purple, scarcely appearing out of the calyx: upper lip erect. Martyn observes, that after flowering time the border of the calyx grows out till it becomes twice as long as the tube, is naked and membranaceous, not villose as in the first species. It is also a native of the island of Candia, flowering from June to August.

Culture.—These sorts are capable of being increased by planting cuttings of the young shoots or branches in a shady border in the early spring, as about April. When the plants are well rooted, they may be removed into the places where they are to remain in the early autumn, with earth about their roots; but it is better to raise them at once in the places where they are to grow: when they grow strongly they should be screened from hard frosts in winter.

They continue the longest in poor dry soils, from their having a less luxuriant growth.

They afford variety in the borders, clumps, and other parts of pleasure grounds.

MARSH-ELDER. See *VIBURNUM*.

MARSH-MALLOW. See *ALTHÆA*.

MARSH-MARYGOLD. See *CALTHA*.

MARTYNIA, a genus containing plants of the tender herbaceous flowery kind.

It belongs to the class and order *Didynamia Angiospermia*, and ranks in the natural order of *Personatae*.

The characters are: that the calyx is a five-cleft perianthium, unequal, shrivelling: the corolla one-petalled, bell-shaped: tube spreading, ventricose, gibbous below at the base, melliferous: border five-cleft, obtuse, spreading: segments almost equal; the lower straight, the lowest more erect, concave, crenate: the stamina have four filiform filaments, curved inwards; the rudiment of a fifth filament within the upper pair of stamens, short like a cusp: anthers connected-converging: the pistillum is an oblong germ: style short, simple, the length of the stamens: stigma two-lobed: the pericarpium is a woody oblong capsule, gibbous, quadangular, two-furrowed on each side, acuminate, with the tip bent back, opening two ways, four or five-celled, inclosing the seeds as in a four-celled nucleus: the seeds several, oblong, berried.

The species cultivated are: 1. *M. diandra*, Two-stamened Martynia; 2. *M. prostrata*, Hairy Martynia; 3. *M. perennis*, Perennial Martynia.

Other species may be cultivated.

The first is a handsome large plant, two feet high, straight, with large leaves, viscid, from small, slender, simple, white, villose hairs, each of which has a pellucid clammy globule at the top: the stem single, round, reddish green: the branches several, brachiate, dichotomous: the root-leaves none: the stem-leaves opposite, angular, with teeth remote by a long sinus, flaccid, green, white from the closeness of the villose hairs, veined; the largest six inches long: petioles on the stem horizontal, on the branches spreading, the same length with the leaf: the flowers several, on short peduncles, hanging down, so that the throat is turned towards the ground, disposed in a thyrse in the forks of the branches, two inches and a half long. It is a native of La Vera Cruz, in New Spain.

The second species is a large plant, two feet high, flexuose, herbaceous, villose, viscid: the stem single, round, pale green: the branches several, scattered, resembling the stem: the root-leaves none: the stem-leaves opposite and alternate, stiffish, waved, veined, yellowish green, five inches long: the petioles horizontal, slightly channelled above, the length of the leaf: the flowers several, peduncled in a loose thyrse in the forks of the branches, two inches long. It is a native of America, flowering from June to August.

The third has a perennial root, thick, fleshy, divided into scaly knots, somewhat like those of Tooth-wort: the stems annual, about a foot high, thick, succulent, purplish: the leaves are oblong, thick, sessile, rough, and of a dark green, on their upper-side, but purplish underneath: the stem is terminated by a short spike of blue bell-shaped flowers, not spreading open so much at the rim as in the first sort. It is a native of Carthagera, in New Spain.

Culture.—The two first sorts may be increased by sowing the seeds in pots filled with light rich mould, in the spring, plunging them in a bark hot-bed, giving water frequently. When the plants have attained a little growth, they should be removed into separate pots of the same sort of earth, replunging them in the bark bed, giving due water and shade, till they become properly rooted, when they must have free air in fine weather: after they are a little advanced in their growth, they should be removed into larger pots, and be replaced in the bark bed in the stove, due room being allowed them. They should be constantly kept in this situation, and be duly watered and supplied with fresh air in warm weather.

The third sort may be raised by dividing the roots, and planting them in the spring about the middle of March, in pots of light rich earth,

and plunged in the bark-bed of the stove. When the plants are up, they should be duly watered in a slight manner, and in warm weather fresh air be freely admitted, keeping them from being shaded by other plants.

The cuttings of the shoots of the young stems planted in pots, and managed in the above manner, will also take root and form plants.

They afford ornament and variety among other stove plants.

MARVEL OF PERU. See MIRABILIS.

MARYGOLD. See CALENDULA.

MASSONIA, a genus containing plants of the herbaceous bulbous-rooted flowery perennial kind.

It belongs to the class and order *Hexamiria Monogynia*, and ranks in the natural order of *Coronariæ*.

The characters are: that there is no calyx: the corolla has six lanceolate petals, spreading, upright, placed externally on the nectary, which is inferior, cylindrical, membranaceous, six-streaked, six-toothed: the stamina six, filiform, incurved, a little longer than the petals, inserted into the teeth of the nectary: anthers ovate, upright, yellow: the pistillum is a superior germ (in respect of the nectary): style awl-shaped, declining, the length of the stamens: stigma simple, acute: the pericarpium is a three-sided capsule, thickening above, obtuse, smooth, three-celled, three-valved, opening longitudinally at the corners: the seeds very many, angular-globular, and smooth.

The species cultivated are: 1. *M. latifolia*, Broad-leaved Massonia; 2. *M. angustifolia*, Narrow-leaved Massonia.

The first has the leaves next the root, one pair, smooth and even: the flowers aggregate, sessile, without any scape: the fruit not berried, but a membranaceous capsule; in which it differs from *Hæmanthus*. It is a native of the Cape, flowering in March and April.

The second species has the same structure; but the leaves are narrow, of an oblong-lanceolate form, and the segments of the corolla bent back at the end; whereas in the first they spread straight out. It is a native of the Cape, flowering in March and April.

Culture.—They may be increased by planting the off-sets from the roots, when the leaves drop off, in pots of sandy earth, plunging them in a hot-bed in the stove.

They are likewise capable of being raised from seeds sown in pots of the same sort of earth, plunging them in a hot-bed.

The plants should afterwards have a free air in the green-house, where they must be kept.

They afford variety in these collections.

MASTICK TREE. See **PISTACIA**.

MAT, GARDEN, a sort of covering formed of bass, which is much used in gardening, for sheltering various sorts of plants in winter and spring, in frosty and other cold weather; and in summer for shading many sorts of young or tender kinds occasionally from the sun; and many other purposes in the different garden departments.

They are of different sorts in regard to size and substance, there being small, middling, and large sizes: but for general use, those called **Russia Mats** are superior, both in size, substance, and durability. It may also be proper to have some of the smaller or middling sizes for particular occasions, and small gardens, in which, for some purposes, they may be more convenient than large ones. They are sold by most of the principal nursery and seedsmen, at from six or eight to twelve or fifteen shillings per dozen, according to size and strength.

They are also of essential use in all hot-bed work, for covering or spreading over the lights or glasses of the frames in the nights, in winter and spring, to exclude the external night cold; also occasionally in the day time in very severe weather, and heavy falls of snow or rain.

Likewise for occasionally covering several sorts of small young esculent plants with, in the full ground in beds and borders, in these seasons; as young lettuces, cauliflowers, small-sallad herbs, early radishes, &c. in the open beds, and under frames and hand-glasses, to defend them from cutting frosts, snow, and other inclement weather: and sometimes in raising, transplanting, or pricking out small or moderate portions of particular sorts of plants, both of the hardy and tender kinds, whether of the esculent or annual flowery kinds in the spring, on beds or borders of natural earth, or in hot-beds, without frames, by being arched over with hoops or rods. They are likewise extremely useful in the spring and summer, in hot, dry, sunny weather, in shading several sorts both in seed-beds before and after the young plants are come up, and in beds of pricked-out small young plants, to shade them from the sun till they take fresh root; as also for shading the glasses of hot-beds occasionally, when the sun is too powerful for particular sorts of plants in the heat of the day, as in Cucumbers, Melons, and various other kinds.

In kitchen and other garden districts furnished with wall-trees, they are of great use in spring to cover the trees of particular sorts with when in blossom, and when the young fruit is setting and advancing in its early growth after the decay and fall of the bloom; by which assistance, in cold winters and springs, when sharp frosts

sometimes prevail, a tolerably good crop is often saved, while in trees fully exposed the whole is cut off by the severity of such weather.

In the flower-garden and pleasure-ground, Mats are also found useful on different occasions; in the former, in sheltering beds of curious sorts of choice flower-plants, and both in their advancing growth, to protect them from cold in winter and spring; and when in full bloom, to shade and screen the flowers from the sun and rain, to preserve their beauty more effectually, and to continue them longer in blow of a fine lively appearance; as well as to cover beds, &c. in raising various tender annual plants from seed in the spring; and in the latter occasionally in winter to defend some kinds of curious tender evergreens, &c. such as some of the *Magnolias*, *Broad-leaved Myrtle*, *Olive*, *Tea Tree*, &c. when standing detached and trained against walls.

And in nurseries, they are of considerable utility in the propagation and culture of numerous sorts of tender curious exotics, in defending them from cold, and shading from scorching sun, while they are in their minor growth, &c. They are necessary also for matting round bundles or baskets of tender or curious plants, when conveyed to a distance.

They are also of great use occasionally in severe winters on such glass-work as green-houses, hot-houses, forcing-frames, &c. in covering the glasses externally on the nights, and occasionally in the day time.

In using these Mats, when the ends are open or loose, they should be secured by tying the end threads or strings of the bass close and firm, otherwise they soon ravel out loose in that part, and are spoiled.

When made use of in the work of covering and shading, &c. they should generally in uncovering, if rendered wet by rain or snow, be spread across some rail, hedge, or fence, &c. to dry, before folding them together, that they may be preserved from rotting, otherwise they will not last long.

These Mats should never have any bass drawn out of them for tying up plants with, as is too commonly the practice, as by such means they are soon spoiled.

MATRICARIA, a genus containing plants of the hardy herbaceous perennial kind.

It belongs to the class and order *Syngenesia Polygamia Superflua*, and ranks in the natural order of *Compositæ Discoidæ*.

The characters are: that the calyx is common hemispherical: scales linear, imbricate, almost equal, not scarious: the corolla compound radiate: corollets hermaphrodite, tubular, numerous,

in a hemispherical disk: females in the ray several: proper of the hermaphrodite funnel-form, five-cleft, spreading: female oblong, three-toothed: the stamina to the hermaphrodites have five capillary filaments, very short: anthers cylindrical, tubular: the pistillum to the hermaphrodites an oblong germ, naked: style filiform, the length of the stamens: stigma bifid, spreading: to the females germ naked: style filiform, almost the length of the hermaphrodite: stigmas two, revolute: there is no pericarpium: calyx unchanged: the seeds solitary, oblong, without any pappus or down, to both sorts of florets: the receptacle naked, and convex.

The species cultivated is *M. parthenium*, Common Feverfew.

It has a perennial or biennial root, composed of a great number of fibres, and spreading wide on every side: the stem from two to three feet high, erect, firm, round, striated, slightly hairy, branched on every side: the leaves petioled, alternate, pale green, soft and tender, pinnatifid with two or three pairs of ovate jagged pinnas, and a larger one terminating, three-lobed, wedge-shaped, the middle lobe trifid, the side-lobes notched, roughish, slightly hairy: when magnified they appear as if sprinkled with minute spangles: the flowering heads solitary, sometimes on simple, but oftener on branched peduncles, forming together a loose umbel or rather corymb, hairy; the peduncles are thickest just beneath the flower, and about two inches long. It is a native of many parts of Europe, flowering in June.

There are several varieties, as with full double flowers, with double flowers, having the florets of the ray plane, of the disk fistular; with very small rays; with very short fistular florets; with naked heads, having no rays; with naked sulphur-coloured heads, and with elegant curled leaves.

Culture.—These plants may be raised from seeds, by parting the roots and cuttings.

The seeds should be sown in the spring, as March, upon a bed of light earth, and, when they are come up, planted out into nursery-beds, at about eight inches asunder, where they may remain till the middle of May when they should be taken up, with a ball of earth to their roots, and planted in the middle of large borders, or other parts, for flowering.

They should not be permitted to seed, as it often weakens and decays the roots; therefore, when their flowers are past, their stems should be cut down, which will cause them to push out fresh heads, whereby the roots may be preserved.

MAURITIA, a genus containing a plant of the exotic tree kind.

It belongs to the *Appendix Palmæ*, and ranks in the natural order of *Palms*.

The characters are: that the male-flowers are in an oblong ament, covered all round with flowers, closely approximating, with blunt scales between the flowers: the calyx is a one-leaved, cup-shaped perianthium, truncated, entire, three-sided, short: the corolla is one-petalled: tube short, the length of the calyx: border three-parted: segments equal, spreading a little, lanceolate, rigid (in a manner woody), blunt: the stamina have six filaments inserted into the throat of the tube, thick, very short: anthers linear, angular, the length of the segments of the corolla; three alternate ones extended between the segments of the corolla, and horizontal; the three others are generally erect, and pressed close to the channel or the segments: female, unknown.

The species is *M. flexuosa*, Maidenhair Tree, or Ginkgo.

It is a singular tree, almost without leaves: the branches are angular, flexuose, smooth, with short joints, thickening upwards, somewhat recurved, terminated by embracing sheaths: with a cup-shaped and sharper knee joint: from the axils of these come out over the whole stem, strobile-shaped aments, in two rows, spreading very much, sessile, with two large upright scales, sickle-shaped upwards at the base: the aments ovate-oblong, cylindric, covered with closely approximating, ferruginous flowers, spreading very much; falling off and leaving the ament, with its scales. It is a native of the woods of Surinam.

Culture.—It may be increased by laying the young branches in the summer season, and when they have stricken root fully, taking them off and planting them with earth about their roots in pots filled with light fresh mould, placing them in the green-house, where they must be kept.

Cuttings of the young shoots may also be planted in pots in the same manner, plunging them in a moderate hot-bed till they have stricken root, when they may be managed as the other plants.

It affords variety in the green-house, and when trained against walls; but in the last case must be sheltered by mats, in severe weather in winter.

MEALY-TREE. See **VIBURNUM**.

MEDEOLA, a genus comprising plants of the herbaceous climbing kind.

It belongs to the class and order *Hexandria Trigynia*, and ranks in the natural order of *Sarmentaceæ*.

The characters are: that there is no calyx,

unless the corolla be called so: the corolla has six petals, ovate-oblong, equal, spreading, revolute: the stamina have six awl-shaped filaments, the length of the corolla: anthers incumbent: the pistillum has the germs, three-horned, ending in styles: stigmas recurved, thickish: the pericarpium is a roundish berry, three-cleft, three-celled: the seeds solitary and heart-shaped.

The species cultivated are: 1. *M. Virginiana*, Virginian Medeola; 2. *M. asparagoides*, Broad-leaved Shrubby Medeola; 3. *M. angustifolia*, Narrow-leaved Shrubby Medeola.

The first has a small scaly root, from which rises a single stalk, about eight inches in height: there is one whorl of leaves, at a small distance from the ground, and at the top are two leaves, standing opposite: between these, come out three slender peduncles, which turn downwards, each sustaining one pale herbaceous flower, with a purple pointal. It is a native of Virginia, flowering in June.

The second species has the root composed of several oblong knobs, which unite at the top, like that of the *Ranunculus*; from which arise two or three stiff winding stalks, dividing into branches, and rising four or five feet in height, when they meet with support: the leaves are sessile, ending in acute points, of a light green beneath, but dark above: the flowers come out from the sides of the stalks, singly, or two on a slender short peduncle: the petals are dull white. It flowers in the beginning of winter, and the seeds become ripe in the spring. It is a native of the Cape.

The third has a root like the second, but the stalks are not so strong; they climb higher, but do not branch so much: the leaves are much longer and narrower, and are of a grayish colour: the flowers come out from the sides of the branches, two or three upon each peduncle: they are of an herbaceous white colour, shaped like those of the second sort, appearing about the same time; but have not produced fruit in this climate. It is likewise a native of the Cape, flowering from December to March.

Culture.—These plants may be increased by planting offsets, taken from the roots in the summer season, about July, in pots filled with good rich light mould, remaining in the open air till autumn, when they should be removed into the green- or hot-house; but the latter when intended to fruit. While the plants have a vigorous growth, they should be frequently refreshed with water; but as the stems decay, very little, especially when placed in an eastern aspect.

The second and third sorts may be raised from seeds, but they commonly remain long in the earth before they come up.

The first sort is sufficiently hardy to stand in the open air during winter.

They afford variety in green-house and stove collections, in the winter season.

MEDICAGO, a genus furnishing plants of the shrubby evergreen and herbaceous annual kinds.

It belongs to the class and order *Diadelphia Decandria*, and ranks in the natural order of *Papilionaceæ* or *Leguminosæ*.

The characters are: that the calyx is a one-leaved perianthium, straight, campanulate-cylindrical, half-five-cleft, acuminate, equal: the corolla papilionaceous: banner ovate, entire; the margins bent in, the whole bent back: wings ovate-oblong, affixed by an appendage to the keel, with the sides converging under the keel: keel oblong, bifid, spreading, blunt, bent down from the pistil, and gaping from the banner: the stamina have diadelphous filaments, united almost to the tops: anthers small: the pistillum is a pedicelled oblong germ, curved in, compressed, involved in the filaments, starting from the keel, bending back the banner, ending in a short, awl-shaped, almost straight style: stigma terminating, very small: the pericarpium is a compressed legume, long, bent in: the seeds several, kidney-shaped or angular.

The species cultivated are: 1. *M. arborea*, Tree Medick, or Moon Trefoil; 2. *M. polymorpha*, Variable Medick, or Snail and Hedge-hog Trefoil.

The first is a shrub growing to the height of from four or five to eight or ten feet, and being covered with a gray bark, the whole has a hoary appearance: the stem divides into many branches, with ternate leaves at each joint, on foot-stalks about an inch in length: there being several of these leaves together, the whole shrub is closely covered with them; and it is never destitute of leaves: the component leaflets are small, lanceolate, (or wedge-shaped, emarginate,) and hoary on their under side: the flowers are produced on peduncles from the side of the branches, four or five together, and are of a bright yellow: the pods contain three or four small seeds. It flowers a great part of the year, and when sheltered is seldom destitute of them; beginning in the open air to flower in April, and continuing till December.

It grows in great plenty in Abruzzo, and Naples.

The second species has an annual, oblong, branched root; the stems more or less procum-

bent, somewhat angular, hoary, from a hand to a foot in length, ternate: leaflets roundish, retuse, subserrate, glaucous-green, petioled: the upper ones smaller, soft, tomentose: the stipules entire or toothed, sessile, in pairs at the base of the petioles: the peduncles axillary, much longer than the leaves, round, pubescent, forming a spike: flowers very small, commonly yellow: the calyx smaller than the corolla, hirsute, green-hoary: the legumes shell-snailled, small, one-celled, of different shades of brown or blackish when ripe, ciliate, aculeate or naked: the seeds ovate, smooth, convex on one side, flat on the other, lemon-coloured. It is a native of the South of Europe.

There are numerous varieties and subvarieties, but the principal are: the Common Snail Medicago, with large smooth pods, shaped and twisted like a snail: the Hedge-hog Medicago, with large prickly snail-shaped pods, armed with spines pointing every way like a hedge-hog; with turbinate pods; with globular pods; with orbicular pods; with long crooked pods; with double pods; with clustered pods; with twisted pods; and with jagged leaves.

Culture.—The first sort may be raised from seeds or cuttings.

The seeds should be sown in the early spring, on a warm border, or in pots of light mould, and plunged in a moderate hot-bed, till the plants have attained a little growth; when they should be gradually hardened to the full air. In both methods the plants should be kept clean, and have protection in the following winter from frost, and in the spring they should be planted out, some into pots to have the management of green-house plants, and others into the borders and nursery-rows, in dry warm situations, the former to remain, and the latter to be occasionally transplanted.

When they are increased by cuttings, they should be planted on a bed of light rich earth, or in pots of the same sort of mould, and plunged in a moderate hot-bed, due shade and water being given; and when they have formed good roots, in the autumn they may be removed into other pots or the situations in which they are to remain, shading and watering them till they are well rooted, when they should be trained up to sticks, to have straight stems and regular heads, their irregular shoots being annually pruned to keep them in order. These plants are found to grow stronger and flower better when kept in warm situations in the open air, than when managed as green-house plants. They should, however, be sheltered in very severe winters.

The second sort and varieties may be raised from

VOL. II.

seed, which should be sown in the early spring months in the places where the plants are to remain, in patches of several seeds, afterwards thinning the plants to two or three of the best, when they require no further culture. It is the double sorts that are chiefly cultivated in the garden.

They both afford variety in the borders and other parts, and the former in the green-house.

MEDLAR. See MESPILUS.

MEDUSA'S HEAD. See EUPHORBIA.

MELASTOMA, a genus containing plants of the evergreen tree and shrub exotic kinds.

It belongs to the class and order *Decandria Monogynia*, and ranks in the natural order of *Calycanthemæ*.

The characters are: that the calyx is a one-leaved, bell-shaped perianthium, ventricose at the base, four or five-cleft, permanent: the corolla has four or five roundish petals, inserted into the throat of the calyx: the stamens have eight or ten filaments, inserted into the calyx, short: anthers long, somewhat curved, upright, one-celled, gaping at top with an oblique hole: scalelets two, very small, diverging, annexed to each filament below the anther, the rudiment of another cell: the pistillum is a roundish germ, in the belly of the calyx: style filiform, straight: stigma blunt or headed: the pericarpium is a two-, three-, four-, or five-celled berry, wrapped up in the calyx, roundish, crowned with a cylindric rim: the seeds very many and nestling.

The species cultivated are: 1. *M. grossularioides*, American Gooseberry of Surinam; 2. *M. holosericea*, Satiny-leaved Melastoma of Brazil.

Other species may be cultivated for variety.

The first seldom grows more than seven or eight feet high, spreading out into many slender branches, covered with a smooth purple bark: the leaves are lanceolate, five inches long, and two broad in the middle, smooth on both sides, entire, acute-pointed: the flowers are produced in pretty long hanging bunches, of an herbaceous colour, with styles stretched out a good length beyond the petals, and permanent: the fruit small and black when ripe. It is a native of Surinam.

The second species has a shrubby stem, rough-haired, with membranaceous corners: the leaves cordate at the base, acuminate, whitish underneath, nine-nerved, with three nerves thicker: the racemes opposite, subdivided, with a sessile flower in the forkings: the last pedicels three-flowered: the corollas rather large: the calyx oblong, five-cleft; segments lanceolate,

O

acute: the petals five, obovate, roundish, blunt, spreading, longer than the segments of the calyx, violet-purple: the filaments ten, the length of the corolla, filiform, purple: the anthers very long, sickle-shaped: the germ oblong: the style long and curved: the stigma thickish: the fruit a berry. It is a native of Brazil.

Culture.—These plants are best obtained by having the entire fruits put up in their native places in dry sand as soon as ripened and immediately forwarded, which as soon as they arrive should be taken out, and the seeds sown in pots of light earth, plunging them in a moderate hot-bed of tanner's bark: when the plants are up, and fit to remove, they should be planted each in a small pot of light earth, re-plunging them into the tan-bed.

They afterwards require the management of other woody stove plants.

They may also be increased by laying the young branches in the spring and by planting cuttings of the young shoots in the summer season in pots, and plunging them in a hot-bed. They must afterwards have the same culture as the others.

MELIA, a genus containing plants of the deciduous and evergreen exotic tree kinds.

It belongs to the class and order *Decandria Monogynia*, and ranks in the natural order of *Trihilatae*.

The characters are: that the calyx is a one-leaved perianthium, very small, five-toothed, upright, blunt: the corolla has five linear-lanceolate petals, spreading, long: nectary cylindric, one-leaved, the length of the corolla, with a ten-toothed mouth: the stamina have ten filaments, very small, inserted within the apex of the nectary: anthers not exceeding the nectary, oblong: the pistillum is a conical germ: style cylindric, the length of the nectary: stigma capitate, with five converging valves: the pericarpium is a globular soft drupe: the seed a roundish nut, five-grooved, five-celled.

The species are: 1. *M. Azedarach*, Common Bead-tree: 2. *M. sempervirens*, Evergreen Bead-tree; 3. *M. Azadirachta*, Indian Evergreen Bead tree.

The first, in its native situation, grows to a large tree, spreading out into many branches: the leaflets are notched and indented on their edges, deep green above, and paler underneath: the flowers come out from the side of the branches in long loose bunches: the petals are blue: the fruit oblong, the size of a small cherry, green at first, but when ripe changing to a pale yellow: the nut four- or five-celled, with one oblong seed in each cell. It flowers in

July, but seldom produces seeds: it drops the leaves in autumn, and puts out fresh ones in the spring: the pulp surrounding the nut is said to be poisonous. The nuts are bored and strung for beads. It is a native of Syria.

The second species, which has generally been regarded as a variety, is thought by Swartz to be a distinct species, differing from that in being smaller and often flowering for two years together: the leaflets, which are bright green, are seldom more than seven, wrinkled a little, deeper and more unequally serrate and acuminate. It is a native of the East Indies.

The third becomes a large tree in India. The stem is thick, the wood of a pale yellow, and the bark of a dark purple colour, and very bitter: the branches extend wide on every side: the leaves are composed of five or six pairs of oblong acute-pointed leaflets, terminated by an odd one; they are serrate, of a light green colour, and of a strong disagreeable odour; they stand upon pretty long foot-stalks, opposite, or alternate: the flowers are produced in long branching panicles from the side of the branches: they are small, white, and sit in small calyxes, cut into five acute segments: fruit oval, the size of small olives, green, turning yellow, and when ripe changing to purple: the pulp is oily, acid, and bitter: the nut is white, and shaped like that of the former.

Culture.—These plants are all capable of being increased by seeds, which in the first sort are obtained from abroad, and should be sown in pots of light rich earth in the spring, plunging them in a hot-bed of tanner's bark or dung, under frame and glasses, giving frequent waterings and fresh air when the plants are come up, being fully exposed in a moderate shade, during the summer, and placed under a frame in the autumn, &c. to have the free air all winter in open weather, and be sheltered from east.

In the following March they may be planted in separate small pots, plunged in a bark-bed, &c. Though this last is not absolutely necessary, when practised it greatly facilitates their rooting and early growth.

When they have been thus managed for three or four years, and shifted occasionally into larger pots; some of the strongest and most woody plants may be planted out in the full ground under a warm wall, or in a dry sheltered part of the shrubbery. The proper season for this work is the first fortnight in April.

Some plants should likewise be placed in pots, to have the management of green-house exotic plants, lest those in the open ground

should be destroyed by the frost during the winter season.

In the second and third sorts, the seeds should be sown in pots and plunged in the bark-bed, and managed nearly as the first sort; but, as being much more tender, must be always kept in pots, and plunged in the tan-bed in the stove during their early growth; afterwards, when they have acquired considerable size and strength, they may be placed in the open air for a month or two in the heat of summer, but the rest of the year be kept in the hot-house: managing them as other woody exotic stove plants.

The last sort is not common in the gardens.

The first sort is proper for shrubberies and other parts in warm situations as well as for the green-house, and the others for stove collections.

MELIANTHUS, a genus containing plants of the perennial exotic kind.

It belongs to the class and order *Didymia Angiospermia*, and ranks in the natural order of *Corydalis*.

The characters are: that the calyx is a large perianthium, five-parted, coloured, unequal: the two upper segments oblong, erect; the lowest very short, like a bag, gibbous downwards; the middle segments opposite interior, lanceolate, the uppermost simple, erect: the corolla has four petals, lanceolate-linear, with the tops reflex, from parallel spreading, turned outwards, forming the lower lip, as the calyx itself does the upper, connected at the sides in the middle: nectary one-leaved, placed within the lowest segment of the calyx, and fastened to it with the receptacle, very short, compressed at the sides, gashed at the edge, turned downwards by the back: the stamina have four awl-shaped filaments, upright, the length of the calyx; the two lower shorter, united at the base: anthers cordate-oblong, four-celled in front: the pistillum is a four-cornered germ, gibbous, four-toothed: style upright awl-shaped, of the same length, and in the same situation with the stamens: stigma four-cleft, with the upper segment larger: the pericarpium is a quadrangular capsule, half-four-cleft, angles sharp, distant: cells inflated: partitions open in the centre for a receptacle of the seeds, gaping between the angles: the seeds in fours, subglobose, annexed to the centre of the capsule.

The species cultivated are: 1. *M. major*, Great Honey-flower; 2. *M. minor*, Small Honey-flower.

The first has a woody, perennial, spreading root: the stems many, woody, four or five feet high, herbaceous towards the top: the

leaves large, embracing the stem at the base, where they have a large single stipule fastened on the upper side of the foot-stalk, with two ears at the base, which also embrace the stem: the leaves have four or five pairs of very large leaflets, deeply jagged into acute segments; and between them runs a leafy jagged border or wing along the upper side of the midrib, so as to connect the leaflets at the base; they are of a gray colour: the spikes are pretty long, springing from between the leaves towards the top of the stalks: the corolla is brown or chocolate colour. It has been remarked by Linnaeus, that when shaken while in flower it distils a shower of nectar. It is a native of the Cape.

The second species rises with round, soft, woody stalks; five or six feet high, sending out two or three branches from the sides: the leaves are not half so large as those of the preceding, deep green on the upper, and whitish on the under side: the flowers come out from the side of the stalks in loose hanging panicles, each sustaining six or eight flowers, smaller than those of the first sort: the lower part of the petals is green, the upper saffron-coloured, and on the outside, in the swelling part of the petals, is a blush of fine red. Mr. Curtis remarks, that the stem, which is shrubby, during the flowering season is apt to exhibit a naked appearance, having then fewer leaves on it, and those not of their full size: that the foliage has an unpleasant smell; and that the nectar does not flow so copiously as in the large sort, but is retained at the bottom of the corolla, and is of a dark brown colour. It is a native of the Cape.

Culture.—These plants may be increased by suckers from the roots and cuttings of the young stalks or branches.

The first sort is best raised by planting the suckers or side-shoots, any time in the spring or summer seasons, choosing such as are furnished with root fibres, in pots, or the places where they are to remain, which, after they are planted and have taken root, require little further care but to keep them clean from weeds. The cuttings may be planted during any of the summer months, due water and shade being given. When they have taken root they should be planted out where they are to remain, or in separate pots, to be managed as green-house plants.

The second sort is raised with more difficulty, and chiefly from cuttings, which should be planted upon an old hot-bed, the heat of which is over, and covered close with bell- or hand-glasses to exclude the air. When they have

taken root they may be planted out in pots and sheltered in the winter under a frame for a year or two till they are become strong, after which they may be set out in a warm border, and be managed in the same manner as the first sort.

They succeed best in a dry soil and warm situation; but some plants should always be kept in pots and treated as green-house plants, lest those in the open ground be destroyed by severe frosts.

They afford ornament and variety in the borders and clumps, as well as among other plants in the green-house.

MELISSA, a genus containing plants of the hardy herbaceous, fibrous-rooted perennial kind.

It belongs to the class and order *Didynamia Gymnospermia*, and ranks in the natural order of *Verticillatae*.

The characters are: that the calyx is a one-leaved perianthium, subcampanulate, dry-scarious, spreading a little, angular, striated, permanent, with a two-lipped mouth: upper lip three-toothed, reflex-spreading, flat; lower lip shorter, sharpish, two-parted: the corolla one-petalled, ringent: tube cylindrical: throat gaping: upper lip shorter, erect, arched, roundish, bifid: lower lip trifid: middle segment larger, cordate: the stamina have four awl-shaped filaments; two the length of the corolla, two shorter by half: anthers small, converging in pairs: the pistillum is a four-cleft germ: style filiform, the length of the corolla, inclining along with the stamens beneath the upper lip of the corolla: stigma slender, bifid, reflex: there is no pericarpium: calyx larger, unchanged, fostering the seeds in its bosom: the seeds four, ovate.

The species cultivated are: 1. *M. officinalis*, Official or common garden Baum or Balm; 2. *M. grandiflora*, Great-flowered Baum; 3. *M. Cretica*, Cretan Baum; 4. *M. fruticosa*, Shrubby Baum.

The first has a perennial root, and an annual stalk, which is square, branching, from two to three feet high: the leaves by pairs at each joint, two inches and a half long, and almost two inches broad at the base, growing narrower towards the top, indented about the edges; the lower ones upon pretty long foot-stalks; flowers grow in loose small bunches from the axils in whorls, upon single peduncles: they are white, or yellowish, and appear in July. It is a native of the southern parts of Europe.

It varies, with variegated leaves, and with the stalks slender, the leaves much shorter, the whole plant hairy, and of a strong disagreeable

odour: the flowers in whorls, sitting pretty close to the branches, and smaller than those of the common sort. This is the Roman Baum.

The second species has a perennial root and an annual stalk, rising about a foot high: the leaves in pairs at each joint, an inch and a half long, and three quarters of an inch broad, serrate, of a lucid green on the upper side, and whitish on the under: single peduncles come out from the axils, half an inch long, and dividing into two smaller ones, each sustaining two flowers upon short separate pedicels: the flowers are large, of a purple colour. It flowers in June, ripening seeds in August, and is a native of Tuscany, &c.

There are varieties with white flowers; with red flowers; and with variegated leaves. They are all inferior to the purple.

The third has slender stems, low, straight, a little woody, and dark purple: the leaves are small, roundish, hoary: the flowers small and white, appearing in June; the seeds ripen in autumn. It seldom continues more than two or three years, and is a native of the South of Europe.

The fourth has also slender shrubby stems, about nine inches long, putting out small, opposite side-branches: the leaves small, hoary, ovate-acuminate: the flowers are in whorled spikes at the end of the stalks: they are small and white or pale purple, appearing in July, and ripening seeds in autumn. The whole plant has a strong scent of pennyroyal, and is of short continuance.

Culture.—The first and second sorts may be readily increased by parting the roots and planting them out in the early autumn, as October, time enough for the offsets to be established before the winter frosts come on. They should be divided into small pieces with three or four buds to each, and the first sort planted two feet a-part in beds of common garden earth, and the second sort in the borders or other parts singly, in larger offset slips. The only culture they afterwards require is to keep them clean from weeds, and to cut off the decayed stalks annually in autumn, digging or stirring the ground between the plants in the common sort.

The third sort may be raised by sowing the seeds in the autumn or spring, or where the seeds are permitted to scatter there will be a sufficient supply of young plants.

The fourth species may also be increased by seeds sown in the spring on beds or in pots, or by cuttings planted in the same manner, in any of the summer months, and shaded from the sun.

They frequently live through the winter in warm borders; but it is always proper to keep a plant or two in pots, sheltered under a frame during that season.

The first sort is useful for various domestic purposes, and the others ornamental in the borders, clumps, and other parts, as well as affording variety among potted plants.

MELITTIS, a genus containing a plant of the flowery perennial kind.

It belongs to the class and order *Didynamia Gymnospermia*, and ranks in the natural order of *Verticillata*.

The characters are: that the calyx is a one-leaved perianthium, bell-shaped, round, straight, with a two-lipped mouth: upper lip higher, emarginate, acute; lower shorter, bifid, acute, with the divisions gaping: the corolla one-petalled, ringent: tube much narrower than the calyx: opening scarcely thicker than the tube: upper lip erect, roundish, entire: lower spreading, trifid, blunt; middle segment larger, flat, entire: the stamina have four filaments, awl-shaped, under the upper lip, the middle ones shorter than the two outer: anthers converging by pairs in form of a cross, bifid, blunt: the pistillum is a blunt germ, four-cleft, villose: style filiform, the length and situation of the stamens: stigma bifid, acute: there is no pericarpium: calyx unchanged, containing the seeds at the bottom: the seeds four.

The species cultivated is: *M. Melissophyllum*, Bastard Baum.

It has a perennial root, sending up in the spring three, four, or more stems, a foot and a half high or more, upright, with a few branches at the base: the whole plant is hairy: the leaves opposite, petioled, ovate, elliptic, or ovate-lanceolate, somewhat pointed, unevenly and bluntly serrate, the serratures terminating in purplish glands, slightly villose, wrinkled: petioles channelled above, hirsute, united at the base; the flowers large, handsome, growing chiefly on one side, in half whorls, about six flowers together, of a purplish white colour. It is a native of several parts of Europe, flowering in May or June.

Much honey is secreted from a gland that encircles the base of the germ; it is a favourite plant with bees.

There is a variety smaller in all respects, with the leaves ovate and heart-shaped, the flowers not so large, and usually of a pale red, but sometimes white, which is a native of Switzerland, &c.

Culture.—These plants are capable of being increased by parting the roots and planting them out early in the autumn where they are to

remain. The roots should not be parted oftener than every third year. When seeds can be procured, they may also be raised by sowing them in the early spring, where they are to remain. The plants succeed best in a loamy soil and eastern aspect.

They afford ornament in the borders and other parts of pleasure-grounds.

MELON. See CUCUMIS.

MELON-GROUND, the space or portion of ground in the kitchen-garden, or other place, appropriated to the culture of Melons and other vegetables that require artificial heat. See GARDEN, and MELONARY.

MELONARY, the portion of ground in the kitchen-garden principally allotted for the business of early and general hot-bed work, in the culture of Melons and Cucumbers as well as occasionally in other framing culture.

These places are mostly inclosed by some sort of fence, and are particularly convenient and useful, as in the practice of hot-bed culture there is unavoidably a considerable littering occasioned at times, by means of the necessary supplies of hot-dung, straw, litter, and other materials, both in the making of the beds and after-culture; which by this means being confined to a particular part, the whole is performed more conveniently, and without incommoding the œconomy of the other parts of the garden.

They are also very useful when properly chosen in the driest and warmest situations, in the advantage of having the hot-beds on dry ground, and sheltered from cutting winds, with the full benefit of the whole day's sun, as well as in being more secure.

In considerable gardens, the places allotted for this use are sometimes of such extent, as to have the hot-houses, or forcing-houses, and other appurtenances of that kind, where culture by artificial heat is required, near together, by which time and trouble is saved.

In the choice of a place for this purpose, some part of the warmest, best-sheltered, dry quarter of the garden, which is well defended from the northerly and north-easterly winds, and where the ground is dry at all seasons, not liable to inundation or the stagnation of water, and conveniently situated for bringing in dung, tan, earth, &c., should be fixed upon.

And if, with these advantages, it lies rather a little higher or very gently sloping towards some lower part, it will be more proper, especially when towards the full sun from rising to setting, so as to admit of ranging the hot-beds longitudinally east and west, or as nearly in that direction as possible. See GARDEN.

The extent or dimensions must be according to

the quantity of hot-bed framing required, as from two or three, to ten, twenty, or thirty frames, or more; and sometimes also for hot-bed ridges for hand-glasses in the same proportions. They may of course be from two or three to five or ten rods square, or to that of a quarter, or half an acre, or more; in which, besides the part immediately allotted for the hot-beds, it is convenient to have room for the previous preparation of the dung, &c. as well as for compost, heaps of earth, &c. in preparation for earthing the hot-beds.

In respect to form, the most eligible shape is that of square, either an equal or an oblong square.

When inclosed, the fences may be six, seven, or eight feet high in the northerly or back part and five or six in front, the sides corresponding, though when extensive they may be nearly of equal height all round.

The internal part, or immediate place for the hot-beds, even when dry, should be a little elevated to throw off the falling wet of heavy rain, &c.; and when unavoidably low, or liable to be wet in winter or spring, be raised, with some dry materials, considerably above the general level, that the hot-beds may stand dry, as well as to afford advantage in performing the business of culture.

The ground for the immediate place of the hot-beds may generally remain even or level; some however form shallow trenches, the width and length of the intended hot-beds, as from six to twelve inches deep, and make the lower part of the bed in the trench; which, however, is more proper in a dry or somewhat elevated situation than in low or wet ground, as water is apt to settle in the bottom, and chill the beds, occasioning the heat to decline suddenly.

Besides, by having the hot-beds wholly above-ground, there is a better opportunity of applying the occasional linings quite from the bottom upwards. See GARDEN, and CUCUMIS.

By proper attention in the construction of the different parts of these grounds and in the building of the fences, they may also be rendered highly useful in raising various kinds of fruit.

MELON-THISTLE. See CACTUS.

MELOPEPO. See CUCURBITA.

MENISPERMUM, a genus containing plants of the hardy climbing kind.

It belongs to the class and order *Dioecia Decandria*, and ranks in the natural order of *Sarmentaceæ*.

The characters are: that the male has the calyx a two-leaved perianthium: leaflets linear, short: the corolla petals outer six, ovate, spreading, equal, inner eight, obcordate, concave, smaller than the outer, four of them in the inner row wider:

the stamina have sixteen filaments, cylindric, a little longer than the corolla: anthers terminating, very short, bluntly four-lobed: female; calyx and corolla as in the male: the stamina have eight filaments, like those of the male: anthers pellucid, barren: the pistillum has two or three germs, ovate, curved inwards, converging, pedicelled: styles solitary, very short, recurved: stigmas bifid, blunt: the pericarpium has two or three berries, roundish-kidney-form, one-celled: the seeds solitary, kidney-form, large.

The species cultivated are: 1. *M. Canadense*, Canadian Moon-seed; 2. *M. Virginicum*, Virginian Moon-seed; 3. *M. Carolinum*, Carolina Moon-seed.

The first has a thick woody root: the stems many, climbing, becoming woody, and rising to the height of twelve or fourteen feet, twisting themselves about the neighbouring plants for support: the leaves are large, smooth, with the footstalk almost in the middle, and a hollow there on the upper side: the flowers come out in loose bunches from the side of the stem: they are of an herbaceous colour, small, and composed of two rows of oblong oval petals: the stem twines in a direction contrary to the sun's apparent motion, and is smooth and even. It is a native of Canada, &c., flowering in June and July.

The second species differs from the first in the shape of the leaves, which are angular and sometimes heart-shaped, but not peltate, having the footstalk at the base: the stems become woody, and rise nearly as high as those of the first sort: they are round, slender, twining: the leaves are alternate, bright green, the form, colour and consistence of Ivy-leaves, on the upper part of the stem entire, as on old Ivy; on the middle and lower part not unfrequently angular, as in young Ivy; although they have very slender hairs on them, yet they have the appearance of being smooth and shining, especially the younger leaves, for the older ones are subhirsute and less shining; underneath they are of a paler green. The flowers and berries differ little from the first sort. It is a native of Virginia, &c.

The third differs from the second sort in its branches not becoming woody as in that: the stems are herbaceous, the leaves entire and hairy, and not more than half so large; nor is the plant so hardy, so that it does not produce flowers in this climate, unless the season be very warm. It is a native of Carolina.

Culture.—The first and second sorts are easily propagated by laying down the branches in the autumn season, and when the layers have made good roots, in the following autumn they may

be separated and planted out where they are to remain. As their branches are weak and slender, they require support; and when planted near trees thrive better than in an open situation.

The third sort may be increased by parting the roots, and planting them out in the spring, a little before the plants begin to shoot, in warm situations where the soil is light, as in strong retentive land the roots are apt to rot. When planted close to a wall exposed to the south or west, their stalks may be fastened against the wall, to prevent their trailing upon the ground; in which situations the plants frequently flower. They should have a little shelter in severe frost in order to preserve their stalks.

They afford ornament and variety as climbers in the shrubberies and other parts.

MENTHA, a genus containing plants of the hardy herbaceous perennial kind.

It belongs to the class and order *Didynamia Gymnospermia*, and ranks in the natural order of *Verticillatæ* or *Labiatæ*.

The characters are: that the calyx is a one-leaved, tubular perianthium, upright, five-toothed, equal, permanent: the corolla one-petalled: petals upright, tubular, a little longer than the calyx: border four-parted, almost equal; the upper segment wider, emarginate: the stamina have four filaments, awl-shaped, upright, distant, the two nearest longer: anthers roundish: the pistillum is a four-cleft germ: style filiform, upright, longer than the corolla: stigma bifid, spreading: there is no pericarpium: calyx upright, with the seeds in the bottom: the seeds four and small.

The species cultivated are: 1. *M. viridis*, Spear Mint; 2. *M. rotundifolia*, Round-leaved Mint; 3. *M. crispa*, Curled Mint; 4. *M. piperita*, Pepper-Mint; 5. *M. gentilis*, Red Mint; 6. *M. Pulegium*, Pennyroyal; 7. *M. cervina*, Hyssop-leaved Mint, or Upright Pennyroyal.

The first has long, creeping, very spreading roots; the stalks are upright, square, single, green, rising two or three feet in height: leaves spear-shaped, serrated, close-sitting, smooth, very green: the stalks are terminated by purplish flowers, in oblong erect spikes: the stamina longer than the corolla, the latter of which is purplish red. It is a native of Britain, &c.

As it is not so hot to the taste as Peppermint, and having a more agreeable flavour than most of the other sorts, it is generally preferred for culinary and other purposes. The leaves and tops are used in spring salads, and eaten as sauce with lamb, and, when dried, in soups, &c.

There are several varieties: as broad-leaved; narrow-leaved; curled-leaved; variegated-leaved; silver-striped-leaved; gold-striped-leaved.

The second species has the stems from two to three feet in height, erect, hairy or shaggy, the hairs pointing more or less downwards: the leaves are somewhat cordate, rugged, strongly and sharply crenate or rather serrate, the teeth and points of the small upper ones being often very taper: the under side is shaggy not hoary, and all the veins are fringed as it were with close hairs: the spikes are several, terminating erect, sharpish, not very densely whorled: the bractes lanceolate, hairy, sharp and projecting: the flowers reddish: the calycine teeth broad at the base; the stamens always much longer than the corolla. It is a native of several parts of Europe, flowering in August and September. It is found in gardens variegated.

The third has the stems hairy, much branched, about the same height with common Spear Mint: the leaves deeply indented on their edges, waved and curled, light green: the flowers purple, growing in thick interrupted spikes at the top of the stalks: the calyx cut almost to the bottom: the style standing out beyond the corolla. It is a native of Denmark, or Siberia.

The fourth species has smooth purple stalks: the leaves are smaller than those of Spear Mint; they are lanceolate, serrate, very dark green, with purple midrib and veins, and they are a little hairy on their under side: the spikes of flowers are shorter and thicker than those of Spear Mint, and are broken or interrupted at bottom, the lower whorls peduncled, distant, consisting of from nine to twelve: the corolla is of a dark purple colour, and the stamens are longer than the corolla.

In external appearance it corresponds with the first sort, for which it may easily be mistaken; but in that the stem is taller, the leaves have scarcely any petioles, and are narrower in proportion to their length, the spikes are longer and composed of more whorls. It is a native of Britain, flowering in August.

The fifth has several erect stems, growing in tufts, about eighteen inches high, with harsh somewhat hairy angles, more or less reddish in the upper part, branched, leafy: the leaves most crowded towards the upper part, sharply serrate, veiny, punctuated with shining dots, having a few short hairs scattered over them, especially about the margin, and along the nerves on the back: their usual scent is much like that of the first sort, but the smell of Mints is very variable. It is a native of several parts of Europe.

There is a variety with the scent of Basil; Orange scented Mint; Gold striped orange Mint; Yellow orange Mint; and Reddish orange Mint.

The sixth species has a fibrous perennial root: the stems smooth, and putting out roots at every joint: the leaves for the most part entire: the flowers towards the upper part of the branches, just above the leaves at each joint, in whorls: the corolla small, pale purple; upper lip entire: the stamens of the same length with the corolla, but the style somewhat longer. It is a native of many parts of Europe, flowering in August and September.

It varies with a white flower, and with the stems erect, nearly a foot high: the leaves longer and narrower: the whorls of flowers much larger: the stamens longer than the corolla: this is Spanish Pennyroyal, which has almost superseded the other sort; the stems being more erect, it is easier to tie in bunches, and it comes earlier to flower, and has a brighter appearance.

The seventh has also erect stems, nearly two feet high, sending out side branches all their length: the leaves are very narrow, and of a thicker substance than those of common Pennyroyal: the whorls of flowers are rather larger, and the stalks are frequently terminated by them: the scent is not quite so strong as that of the sixth sort. It flowers about the same time, and is a native of the South of France and Italy.

There is a variety with white flowers, growing taller than the common one with purple flowers, which is by some preferred to the sixth sort for medicinal use, and called Hart's Pennyroyal.

Culture in the mint kind.—These plants may all be increased with facility by young offset plants or shoots, or by parting their roots, and planting them out in the spring, or by planting cuttings during any of the summer months in a moist soil. After the cuttings are planted, when the season is dry, they should be often watered until they have taken root; when they require no further care, but to be kept clean from weeds. The best method is to plant them in beds about four feet wide, allowing a path about two feet broad between them, to water, weed, and cut the plants; being set four or five inches or more distant in the rows, as the plants spread much at their roots; on which account the beds should not stand longer than three years before planting them again, as by that time the roots become so closely matted, as to rot and decay each other when they stand longer.

The general culture is that of clearing them

from weeds in spring and summer, cutting down all the remaining stalks annually in autumn; clearing them of all weeds; digging the alleys, and spreading a little of the earth over the beds.

Plantations thus formed will afford several cuttings every summer, when only wanted young for use, for culinary purposes; but when for drying to keep in winter, or green for distilling or medicinal use, the plants should generally be suffered to stand until nearly full grown, and they are just coming into flower; which being then cut down close, the roots send up another crop fit for cutting again in the beginning of autumn, or towards Michaelmas; each general cutting being always made as close to the ground as possible.

Forcing Mint on hot-beds.—When it is much wanted for salads in the winter and early spring seasons, a hot-bed should be made for this purpose, any time after November till the spring, about two feet thick of dung, covering it with garden-frames and glasses, or with mats, on arched sticks, which should then be earthed over with rich mould, six inches thick; when a quantity of the roots should be taken up from a bed and planted pretty close together upon the surface of the bed, moulding them over an inch deep with fine earth, putting on the lights, or other coverings, keeping them close in the nights and in bad weather, but admitting fresh air in mild weather. The plants soon come up, when continue to admit fresh air in fine weather, and give moderate waterings, and they will soon be ready to have their young green tops gathered for use.

When the plants are two or three inches high, they are ready for being cropped, after which they readily break out again, and fresh shoots rise from the bottom; so that the same bed furnishes fresh supplies a long time; two beds, made at different times, being generally sufficient for the whole winter use.

In this way Mint may be obtained young and green from the time that in the natural ground goes off in autumn until it comes in again in the spring season.

It may also be procured by planting some roots thick in large pots, and placing them in a hot-house, as they quickly shoot and furnish plants of young green Mint.

Where this practice is much attended to, small fresh plantations should be made annually in the open ground for the purpose of furnishing a sufficiency of roots, proper for taking up at forcing time, without disturbing those of the principal crops.

Culture in the Pennyroyal kinds.—These may

be increased in the same manner as above, and also by their creeping stems, which should be cut off and planted out in fresh beds, allowing at least a foot distance every way. The young shoots planted in the spring in the same way also take root like the other sorts.

The proper time for this work is in the early autumn, that the plants may be well rooted before winter.

In this way the plants are much stronger and produce larger crops than when planted out in the spring. When the roots remain so close as is generally the case, they are apt to rot in the winter season. They succeed best in a moist strong soil.

Some of the species and varieties may be introduced in the borders and other parts of pleasure-grounds, for ornament and variety.

MESEMBRYANTHEMUM, a genus containing plants of the succulent flowery exotic kinds.

It belongs to the class and order *Icosandria Pentagynia*, and ranks in the natural order of *Succulentæ*.

The characters are: that the calyx is a one-leaved perianthium, five-cleft, superior, acute, spreading, permanent: the corolla is one-petaled: petals lanceolate-linear, very numerous, in several rows, a little longer than the calyx, slightly united at the claws into one: the stamina have numerous capillary filaments, the length of the calyx: anthers incumbent: the pistillum is an inferior germ, with five blunt angles: styles commonly five, awl-shaped, upright, and then bent back: stigmas simple: the pericarpium is a fleshy capsule, roundish, the navel marked with rays; the cells corresponding with the styles in number: the seeds very many and roundish.

The species cultivated are: 1. *M. crystallinum*, Diamond Fig Marigold, or Ice Plant; 2. *M. pinnatifidum*, Pinnated Fig Marigold; 3. *M. Tripolium*, Plane-leaved Fig Marigold; 4. *M. caducum*, Small-flowered Fig Marigold; 5. *M. pupulosum*, Angular-stalked Fig Marigold; 6. *M. geniculiflorum*, Jointed Fig Marigold; 7. *M. noctiflorum*, Night-flowering Fig Marigold; 8. *M. splendens*, Shining Fig Marigold; 9. *M. umbellatum*, Umbelled Fig Marigold; 10. *M. expansum*, Houseleek-leaved Fig Marigold; 11. *M. culumiforme*, Quill-leaved Fig Marigold; 12. *M. bellidiflorum*, Daisy-flowered Fig Marigold; 13. *M. deltoides*, Delta-leaved Fig Marigold; 14. *M. barbatum*, Bearded Fig Marigold; 15. *M. hispidum*, Bristly Fig Marigold; 16. *M. villosum*, Hairy-stalked Fig Marigold; 17. *M. scabrum*, Rugged Fig Marigold; 18. *M. reptans*, Creeping Fig Mari-

gold; 19. *M. uncinatum*, Hook-leaved Fig Marigold; 20. *M. spinosum*, Thorny Fig Marigold; 21. *M. tuberosum*, Tuberous-rooted Fig Marigold; 22. *M. tenuifolium*, Slender-leaved Fig Marigold; 23. *M. stipulaceum*, Upright-shrubby Fig Marigold; 24. *M. crassifolium*, Thick-leaved Fig Marigold; 25. *M. falcatum*, Sickle-leaved Fig Marigold; 26. *M. glomeratum*, Clustered Fig Marigold; 27. *M. bicolorum*, Two-coloured Fig Marigold; 28. *M. serratum*, Serrate-leaved Fig Marigold; 29. *M. micans*, Glittering Fig Marigold; 30. *M. nericulatum*, Spit-leaved Fig Marigold; 31. *M. glaucum*, Glaucous-leaved Fig Marigold; 32. *M. corniculatum*, Horned Fig Marigold; 33. *M. ringens*, Ringent Fig Marigold; 34. *M. dolabriforme*, Hatchet-leaved Fig Marigold; 35. *M. difforme*, Various-leaved Fig Marigold; 36. *M. albidum*, White Fig Marigold; 37. *M. linguiforme*, Tongue-leaved Fig Marigold; 38. *M. pugioniforme*, Dagger-leaved Fig Marigold; 39. *M. tortuosum*, Twisted-leaved Fig Marigold; 40. *M. emarginatum*, Notch-flowered Fig Marigold; 41. *M. bracteatum*, Bracted Fig Marigold.

There are other species that may be cultivated.

The first is an annual plant, distinguished by its leaves and stalks being closely covered with pellucid pimples full of moisture, which when the sun shines on them reflect the light, and appear like small bubbles of ice, whence it is called the Ice Plant: others name it the Diamond Plant, or Diamond Ficoides. The stem has opposite and alternate cylindrical branches, which, when luxuriant, trail upon the ground, and are from one to two feet long. The first four or six leaves are opposite, each pair crossing the other, very lax and succulent, waved, blunt, attenuated or wedge-shaped at the base, and connate, rather keeled underneath, especially at the base, with a slight corresponding channel along the centre of the upper surface, which is covered with less and duller pimples than any other part of the plant: the margin is regularly edged, with globular papule or pimples, which are less than those on the stems: the upper leaves are alternate, growing less and less, nearly sessile, small: the peduncles extremely short or none, alternate, from the axils of the upper leaves: the segments of the calyx unequal, three of them large and leafy, beset with pilose pimples, and acutely pointed; the two inner much smaller, frequently coloured with a purplish tinge, acute at the points: the petals very narrow, blush-coloured without, whitish within, sometimes entirely white. It is a native of Greece, flowering in July and August.

The second species is an annual root, not much branched, of short duration: the whole plant is sprinkled over with glittering particles, like the Ice-plant, to which it bears some affinity in its duration: the stems are branching, of a bright red colour, trailing: the leaves yellowish-green, opposite, attenuated at the base: the flowers small, axillary, solitary, on longish peduncles, yellow: the calycine segments unequal, three being short, two longer and broader: the petals numerous, scarcely equal to the longest segments of the calyx, linear, expanding in the afternoon: the filaments numerous, yellow: the anthers yellow: the germ roundish: capsule obtuse-angled, obtruncate: the seeds numerous, small, roundish, and brown. Introduced from the Cape, flowering in July and August.

The third species has a biennial root: the stems are prostrate, smooth, finally terminating in flowers: the lower leaves many, almost as long as the stems, resembling those of *Aster Tripolium*, but thicker and more succulent: among these spring three or four stems, sometimes more round, and having two or three joints, at each of which are two smaller leaves at the lower, and three or four at the upper joints: the surface in all smooth and even, and very minute white teeth about the edge, more perceptible in the smaller leaves, and the lower part of the others: the flowers are usually solitary, silvery white, opening in the middle of the day, and of short duration. It is a native of the Cape, flowering from June to September.

The fourth is a biennial plant. A native of the Cape, flowering in July and August.

The fifth species has a biennial root: the stem is short, nearly the thickness of the little finger: the branches are opposite, spreading very much, obscurely angular, or round, herbaceous, green, the lower ones procumbent, and a foot and half long: the leaves thick, narrowing into a short petiole, subsessile, entire, flat, somewhat waved, opposite on the branches, at the flowers single; that is, the flowers come out singly on a peduncle opposite to a leaf; these, the stems, peduncles, calyxes, and germs, are covered with very minute shining dots, which when examined with a magnifier appear to be clear drops like ice: the flowers have no scent, and are open from three to six in the afternoon. It is a native of the Cape, flowering from April to October.

In the sixth the plant whilst young is herbaceous, but becoming shrubby by age: the trunk is then woody, a finger or more in thickness, covered with a brownish ash-coloured bark: the branches are decumbent, divaricating whilst

young, cylindric, tender, covered with minute pimples, dark green, thick, fleshy, the bark when old becoming somewhat woody, and assuming various flexuose contorted directions: all the branches are nearly of the same thickness; but the upper ones are shorter, and more woody next the stem: the leaves are mostly opposite, but not always so, especially on the flowering branches, smooth, cylindric, convex beneath, slightly channelled above, minutely pimpled: the flowers are small. It is a native of the Cape, flowering from June to August.

In the seventh, the trunk, which attains the thickness of the little finger, is smooth and even, covered with a bay-coloured bark, and has frequent joints where branches have fallen: the branches are opposite, spreading irregularly, and decumbent from the weight of the leaves: the leaves pale green and slightly glaucous, obtusely triangular, smooth and even, opaque, minutely and thickly dotted so as to make a very fine net: the lower ones longer; their upper ones, whence the peduncles arise, shorter and thicker: the calyx four-cleft: the petals narrow, the inner ones gradually shorter, inwardly white, outwardly purple: the flowers are closed during the day, open in the evening, and continue so during the night, at which time they are very sweet. It is a native of the Cape, flowering from June to August.

There is a variety in which the flowers are somewhat larger, and of a very pale yellow on the outside.

The eighth species has woody stems, a foot and more in length, with many short branches and clustered leaves, with which they are so loaded that they cannot support themselves: the leaves are short, bluntly three-sided, thick, smooth, and shining, pale green, scarcely if at all glaucous, with a few thick green dots: the flowers solitary, at the ends of the branchlets, on very short peduncles, large, whitish or very pale yellow within, reddish on the outside and at the tips: the petals very narrow, the inner ones gradually smaller: they appear in July and August, and open before and after noon when the sun shines, opening and closing several times, and finally closing about the fruit, which is ovate, with five lines or angles, five-celled. It is a native of the Cape.

The ninth has woody stems, forming a regularly branched handsome shrub, standing without support, with a stout stem, from two to three feet high and even more: the branches many, spreading every way, having four lines running along them, which give them the appearance of being quadrangular: the leaves are subtri-

quetrous, wrinkled, bending this way and that, somewhat resembling bulls' horns, glaucous, except the younger ones, which are green and less wrinkled; when held up to the light they appear to have innumerable pores: from one axil of each pair of leaves, sometimes from both, one pair of leaves usually springs, which becomes a shoot, with several pairs of leaves on it: the flowers terminating, white, opening when the sun shines, from seven or eight in the morning to two or three in the afternoon, and smelling like those of May- or White-thorn. It is a native of the Cape, flowering from June to September.

The tenth has the stems and branches irregular and distorted, as in the thirty-ninth sort, from which, however, it differs in being somewhat higher and more branched; the branches interwoven, less woody, but softer and more fleshy, with the bark smoother and of a paler yellow; the leaves greener, something wider and thinner, with the ridge on the outer and the groove on the inner part more conspicuous, though less concave; the dots rather oblong than round, shining like silver in the sunshine; they are not produced in bundles, as in that sort, but more loosely, and decussated: the flowers are somewhat larger and paler: the petals rather wider, becoming yellowish with age. It is a native of the Cape, flowering in July and August.

In the eleventh the leaves are numerous, either upright or bending upwards, rigid, thick, and fleshy, about a finger's length, appearing to be round, but slightly flattened on the inside, especially near the base; they are deep green and glaucous, thickly set with small green dots and some transverse lines, pointed at the end; the point purple or green: the flowers solitary, on a short scape from the centre of the plant, large: the calycine segments are unequal: the petals very narrow, white, shining like silver in the sun, void of scent, opening about noon in July, August, and September. It is a native of the Cape.

The twelfth species has the leaves clustered, decussated, from an inch to two inches in length, deeply glaucous, flat above, but below produced into a sharpish back, towards the end, both above and below, or on all the sides armed with stiffish sharp toothlets; they are smooth, and do not appear to be dotted unless they are held up to the light, but they have a few transverse wrinkles: the peduncles are from an inch to an inch and half and two inches in height, tender, round, usually leafless, but sometimes having a pair of leaves: the flowers are solitary, terminating, the form and size of a Daisy,

whitish with a tinge of purple, and streaked with a purple line along the middle of each petal both within and without; they spread out regularly in two or three rows, and are sometimes entire, sometimes cut a little at the end, opening about noon. It is a native of the Cape, flowering from June to August.

The thirteenth has the peduncles one-flowered, two-leaved: the corollas pale purple, sweet-smelling, not longer than the calyx: the stamens white, upright, and forming a cone: the anthers are yellow: the flowers open in the morning as soon as the sun shines strongly upon them. It is a native of the Cape.

There are different varieties; as the Great Delta-leaved, the Small Delta-leaved Marigold.

In the fourteenth species, the leaflets of the calyx being bearded at the tip, as well as the leaves of the plant, show the origin of the perianthium. The least interior petals, which surround the stamens, are white. It is a native of the Cape.

There are several varieties; as the shrubby, bearded, the small dwarf-bearded, and the great dwarf-bearded.

The fifteenth has the peduncle very rugged downwards, rather to the sight than the touch: the calyx is awnless: the flower is sweet-smelling, very like that of the preceding, from which perhaps it originally sprung, losing the beard of the leaves, and having it scattered over the stem. It is a native of the Cape, flowering the greater part of the year.

There are different varieties; as the purple flowered, the pale flowered, and the striped flowered.

The sixteenth species has the leaves linear, semicylindric, channelled-flat, opaque, with villose hairs scattered over them, especially at the base: the stem is pubescent, with villose hairs scarcely standing out: the plant is hairy, prostrate, finally shrubby: the branches in distant pairs, crossing each other, axillary, cylindrical, covered with the permanent, cylindrical, hairy sheaths of the connate leaves, whose hairs are not very thick set, but short, white, and rather pressed to the stem; some of them expanding, but pointed upwards: the leaves are less succulent than those of any other species, connate, but appearing distinct, unless attentively examined; they are linear, scarcely pimpled, or, if so, the pimples are extremely minute, shining in the sun, and of a dark green colour; they are channelled above, with a convex or rounded keel, slightly attenuated both ways, rather dilating again at the very base, and embracing the stem, where they are quite destitute of succulency, and slightly membranaceous at

the edges, with a white midrib: the membrane at the base is ciliate; the rest of the leaf nearly smooth, or having distant small white hairs scattered over both sides: the flowers are solitary, terminating, rarely seen, opening to a very warm sun only in the forenoon. It is a native of the Cape.

The seventeenth species has woody stems, at bottom bay: the branches yellowish-brown, procumbent, round at bottom, but somewhat angular above: the peduncles, however, are round: the leaves are acutely triquetrous, glaucous, somewhat shorter and thicker, rougher and more rigid, with frequent tubercles larger and whiter, especially on the back, than in the fortieth sort: the flowers are solitary, few (two or three), violet purple and shining, but becoming paler, opening two or three times, before and after noon: the petals mostly of the same size, entire or slightly cloven at the end, firmly connected at the base; they end suddenly in filaments, which are not scattered, but collected into a head about the stamens, like a crown. It is a native of the Cape.

The eighteenth has the leaves between papulose and tubercled; much rougher, more glaucous, and more acutely pointed, than in any other reptant species: the branches are angular, and finally somewhat woody: in its triquetrous leaves and reptant stems it is allied to the twenty-fourth sort. In the open air it will extend the branches above a foot and a half every way, and they are fixed firmly to the ground at every joint by strong fibres. It is a native of the Cape, flowering in July and August.

The nineteenth species has the stems slender and round: the branches rather frequent, reclining, with much smaller and more recurved leaves: having only one short spinule at the back: they end in a spinule short and whitish: the stems and branches, though rigid, are procumbent: the leaves, and internodes, which are elongations of the leaves, investing the stems, are dotted with small dots of a fuller glaucous green colour, and not so white: the bark of the stem rather of a yellow and brown dusky whitish colour: the internodes are thickened above, and narrower beneath: the flowers are axillary, on leafy peduncles. It is a native of the Cape, flowering from June to August.

There are different varieties.

The twentieth is an upright thorny shrub, from two to three feet high, much branched: the branches opposite, axillary, ascending, roundish-compressed, with a smooth cinereous bark, throwing out in various places branching spines: the leaves are in pairs, at an interval of an inch or an inch and half, glaucous, with fre-

quent green dots, pellucid when held up to the light; all the angles blunt, slightly swelled at the inner bases, very firm to the touch, terminating in a very small white cartilaginous point, or harmless bristle: the upper leaves are much shorter: the spines appear as if terminating, but soon cease to be so, from the protrusion of young shoots; they are branched, nearly horizontal, divaricating and trichotomous, each from half an inch to an inch in length, awl-shaped, very sharp, resembling those of the common Hawthorn, but not so strong or pungent, covered with a grayish bark, and beset with a pair of distinct, opposite, chiefly barren leaves, like those of the branches, but only a-third of the size: the flowers small, pale violet purple, on slender, leafless, green peduncles. It is a native of the Cape.

The twenty-first species forms a low, much branched, spreading shrub; and, when old, has a very large tuberous root, sometimes as big as a man's head, partly protruded above the surface: the stem woody, very thick at bottom, covered with a bay-coloured bark: the branches bending, entwined: the leaves short, bluntly triquetrous, with the back convex, the inner or upper surface somewhat swelling, subglaucous, with silver dots, so small as not to be visible except when the sun shines: the flowers are at the ends of the branches, on slender cinereous, or reddish peduncles; are small, of a pale red or vinous colour: petals not numerous, broadish, blunt, equal in size: the stamens collected into a bottle in the middle. It flowers about noon, and is a native of the Cape, flowering from June to September.

It is observed, that in old plants the extreme branches sometimes become thorny; which thorns are the peduncles of the preceding year; thorns also sometimes come out from the forkings of the branches, instead of flowers.

The twenty-second has the stems woody, procumbent, slender, round, with a yellowish bark: the branches from each of the upper axils: the leaves on the inner surface flat, on the outer convex, bright green, inclining to gray, from their slenderness often hanging down, appearing dotted when held up to the light: the flowers at the ends of the branches solitary, on long slender peduncles; they are large, especially on young plants, pale scarlet, shining, and appearing powdered with gold dust in full sunshine: the petals very numerous; the inner ones gradually smaller, entire or cuspidate at the end, sometimes slightly bifid, cohering at bottom: the flowers abundant, and opening several days successively about noon, especially in June.

According to Mr. Haworth, in many stages of

its growth it is very liable to be taken for the twenty-seventh sort, and that it frequently emits roots from the joints of the stems, and thereby becomes creeping. It is a native of the Cape, flowering from June to September.

The twenty-third species is an upright plant, woody, firm, growing to a larger size than most of the species: the flowering-stem is rigid and somewhat gray: the branches axillary, opposite, from erect spreading, crossing each other in pairs, and beset thickly with young leaves on their first outset, whitish or glaucous, but finally brownish, gradually shorter upwards, forming a beautiful pyramidal glaucous plant, well covered with fine leaves; these when full grown are from two to three inches long, slightly curved upwards or falcate, very glaucous, crossing each other in pairs; very much compressed at the sides, having pellucid dots scattered over them, flattish above and mucronate: the flowers terminating in a sort of corymb, large, showy, purple. It is a native of the Cape.

The twenty-fourth has the stems a palm or long span in length, creeping, when young herbaceous and soft, three-sided, green, frequently purple next the sun; when old, more round, still not woody but soft, tough, and fungous, covered with a cinereous bark: the leaves are usually in the same plane, or not decussated, divaricating, or not approximating like many of the other species, thick, succulent, bluntly three-sided, smooth and somewhat shining, green: the flowers on short peduncles, sometimes naked, but more frequently with a pair of leaves on them; solitary, small, violet purple: the petals not very numerous: the stamens many, short, not very much scattered, but not collected into a head or upright. It creeps so much that it seldom flowers, and when it does the flowers do not continue long. It is a native of the Cape.

The twenty-fifth species is a very low, bushy, divaricating almost decumbent shrub, rarely more than six or eight inches high: the branches are opposite, slightly angular, axillary, divaricating, and densely crowded: the leaves very minute and much crowded, glaucous, having smooth pellucid dots, attenuated at the base, very gibbous on the keel, sharply incurved or falcate, near a quarter of an inch long, and ending in an acute, white, just perceptible, bristly point in the direction of the leaves: the flowers are purple, large, solitary, opening in the morning, on short terminating peduncles: the leaves are sometimes so much incurved as to form half a circle, and are remarkably small. It is a native of the Cape.

The twenty-sixth is a small, very bushy, rather glaucous shrub, from six inches to a foot or more in height: the branches almost upright, or often diffuse and panicled, round whilst young, slightly angular when old, covered with a brown bark, for the most part opposite and crowded: the leaves are also opposite and crowded, rather glaucous, having pellucid spots, usually distinct, but sometimes confluent; they are subtrigonal with blunt angles, awl-shaped, attenuated at the base, slightly incurved, sometimes almost sabre-shaped, from three quarters of an inch to an inch and half in length: the flowers are very numerous, reddish purple, like those of the thirteenth sort but more handsome, expanding in the fore part of the day in such profusion as often to cover the surface of the plant: petals linear, numerous. It is a native of the Cape, and flowers from June to August.

It is very variable, assuming different appearances, according to its treatment, and the different stages of its growth: its very numerous beautiful purple flowers, covering the whole plant, and produced every season, make it a valuable species.

The twenty-seventh species grows up into a long, slender, and not much branched shrub, from a foot to two feet high and more: the leaves are slender, oblong, bluntly three-sided, green, not glaucous, rugged to the sight, not the touch, with frequent green tubercles, which when held to the light appear whitish and pellucid: similar tubercles are observed in the lower part of the fruit: the flowers terminating, middle-sized, golden within, red on the outside. It is a native of the Cape, flowering from May to September.

The twenty-eighth is an elegant species, three quarters of a yard in height, with woody stems, not so thick as the little finger, and not much branched, procumbent, covered with an ash-coloured bark: the flowers are on the upper branches, solitary, terminating, large, of an elegant yellow colour, composed of two or three rows of petals, which are blunt, entire, and sometimes jagged, the outer longer and flat, the inner suddenly shorter, more erect, concave, and at their base a circle of saffron-coloured anthers on very short filaments; the bottom of the flower being void, smooth, and even, hollowed out like a dish: they open several times from eight in the morning to three or four in the afternoon if the sun shines, and have a little smell. It is a native of the Cape, flowering in June.

The twenty-ninth species has stems from a foot to two feet in height, procumbent, woody, and much branched: the branches are round,

slender: the leaves in pairs, at an inch or an inch and half distance, an inch in length, thickish, on an old plant narrower and shorter, on a young one longer and thicker, not quite round, but obtusely triangular, with the angles, however, so blunt that they are rather cylindric than three-sided; are overspread with glittering spangles of a greenish yellow colour: the stems and lower branches are bay-coloured and smooth; the upper ones reddish brown, rough to the touch, with many whitish dots, which were originally spangles: the peduncles and calyxes shine with spangles like those of the leaves, but thicker: the flowers are terminating, on peduncles from an inch to an inch and half in length; they are large, concave, with the margin bent back, composed of numerous petals, cohering to the base, gradually smaller, and filamentose in the middle, of a dirty red colour on the outside, but within very dark orange-coloured, deepest at the edge; the narrow middle petals next the white filaments being very dark, by which it is easily distinguished from the other sorts. It is a native of the Cape, flowering from May to August.

It varies with paler smaller flowers.

The thirtieth has the stem woody, from a foot to two feet in height, covered with an ash-coloured bark, deformed by age with irregular wide fissures, knotted and jointed, divided and subdivided into several opposite branches: the leaves so bluntly triangular as to appear to be round, an inch and half or two inches in length, the size of a swan's quill, with dense bundles of other leaves coming out from the axils, glaucous, smooth, appearing pellucid when held up to the light, purple at the end, as are also the branches: the branches and leaves are at short intervals; and, affecting an upright position, this plant has the appearance of a shrub, though probably it would be weighed down by the number and size of the leaves and branches: the flowers are in a sort of umbel at the ends of the branches, from the axils of the leaves, small, pale yellow, and sweet smelling. It is a native of the Cape, flowering in May and June.

It varies with shorter and more manifestly three-sided leaves and fewer flowers.

The thirty-first species has the stems half a yard high and more, woody, with frequent joints, ash-coloured, with fissures at bottom, bay-coloured and more smooth above: the lower and middle branches are twisted, the upper ones are straight and little divided: the peduncles an inch and half or two inches long: the flowers large, pale yellow, or sulphur-coloured on both sides, sometimes slightly tinged with

red on the outside: the petals long, narrow, cuspid, with smaller ones interspersed among the others: they remain expanded only a few hours, and contract about noon: but open several times, and have a succession during the summer months. According to Mr. Haworth, it is a strong upright shrub, the flowers being produced only by old plants, and by them but sparingly. It is a native of the Cape, flowering in June and July.

The thirty-second species has the stems longer, less pressed to the ground than the variety below: all the leaves at the joints are very long, more thick and glaucous: the peduncles not naked, but surrounded by a pair of short leaves: the flower of a deeper yellow colour, with a red line along the back: the stamens numerous, neither collected nor much scattered: yellowish, and whitish anthers: the styles very many, (according to Linnæus, ten) reddish, slender, villose: the capsules round, depressed, fifteen- or sixteen-celled, with a crown on the top of the same number of rays: the leaves which spring from the axils of the larger ones are less frequent and less bent in; but these younger leaves have the angles more acute, and are more glaucous than the longer leaves at the joints, which the nearer they are to the root, the paler and more flaccid they seem to be; the rest are more rigid and succulent, not wrinkled, and scarcely dotted, but the lower ones have transverse lines on their flat sides, are somewhat wrinkled, and much dotted underneath: the flowers are flat, and continue some days expanding about noon.

There is a variety which throws out many procumbent branches, tough at the lower part, but not properly woody, herbaceous at the upper part, about three inches in length, round or slightly angular, jointed at short intervals, with bluntly triangular leaves, from which other leaves spring in bundles, of the same form, but shorter; the root-leaves and those at the base of the branches remarkably long: the leaves bend like the horns of kine, whence the trivial name; they are somewhat glaucous, become soft and flaccid, and then appear marked with many lines and dots: the peduncles six inches in length, or nearly so, and naked: the flowers the size and almost the form of those of Dandelion, but paler, or sulphur-coloured, composed of numerous petals, of which the inner ones are shorter, with a red purple streak running along the middle on the outside, the same tinge appearing at the extremity and base of the petals. It is a native of the Cape.

The thirty-third is stemless whilst young, but acquires by age considerable trailing woody

stems: the leaves are connate, spreading, glaucous, opaque, not marked with lucid dots, somewhat sabre-shaped, or attenuate from the middle downwards to the base, where they are semi-cylindric; thickening towards the points, where they are triquetrous, with a sharp keel, and sides edged with irregular harmless teeth; terminating in a similar tooth, placed on the inner side: the flowers are large, showy, yellow, opening in the afternoon, and closing in the evening. It is a native of the Cape, flowering from May to July.

There is a variety which is entirely sessile, of a whitish glaucous colour, with the leaves paler at the base, with frequent round whitish dots, especially towards the end; they are shorter than those of the preceding, more resupine, less triquetrous, but with a rounder back, and more frequent, longer, incurved prickles, terminated by slender harmless spinules, which are sometimes white, sometimes reddish: the leaves have a white line at the end, which is continued towards the back: there is first a flower in the middle, and afterwards several come out successively at the sides, all sessile. It is called *Cat-Chap* Marigold.

Mr. Haworth has two other varieties; the *Tiger-Chap* Fig-Marigold, which is stemless in all the stages of its growth; being more succulent and gross than the following: the leaves are rather shorter, beset with much longer hairs on the sides, and having numerous whitish spots: the flowers are sessile, yellow, and large;—and the *Mouse-Chap* Fig-Marigold, in which the branches in very old plants are some inches long, and numerous, forming a fine tufted plant: the leaves connate, when young resembling the gaping jaws of a small quadruped, the denticulations on each side resembling teeth; when old, the leaves spread out, and are even recurved; all very glaucous, only about a fourth part of the size of the others, and often roughly dotted: the dots lucid, elevated into small tubercles: the flowers small and of a yellow colour.

The thirty-fourth species at first is a low plant, but it becomes larger and stronger; it does not however rise above a long span in height in six years: the stem is then thick and woody, and several reclining twisted branches spring from it alternately, covered with a dusky reddish bark, smooth, but transversely chinked and irregular; at the end of which come out several leaves disposed crosswise; they are thickish, bluntly flat at top, with a roundish back below, more compressed towards the end, and terminating in a process at the lower part; their colour is deep glaucous green, except the old ones, which are

yellowish, and when dry, brown: the whole covered with frequent green dots, pellucid when held up to the light, protuberant towards the end of the leaves, and rendering them somewhat rugged there: the peduncles an inch and half or two inches long, bracteate: the flowers opening in the afternoon, (about four o'clock) coming out frequently several from the same peduncle, but much smaller, and of a paler yellow colour than in the *Dog-Chap* Fig-Marigold. It is a native of the Cape, flowering from May to July.

The thirty-fifth is a middle sort, between the caulescent and sessile ones, properly belonging to those which are procumbent, and acquiring by age woody branches, short and pressed to the ground, from which, at short distances, and on short slender woody petioles, of a dusky pale brown colour, spring thick leaves in clusters, bright green and shining, triquetrous inclining to round, wider towards the base, and somewhat flattened on the upper part, the lower part rounded, towards the middle, where the flat part ends; some short processes come out on both sides, sometimes on one side only, and sometimes they are wholly wanting; hence towards the point the leaves take a different form, and have the sides from round flattened; they are not however broad and flat, but triquetrous-cylindric. It is a circumstance peculiar to these leaves, that one side of each is much shorter than the other, and hence they are called difform: they have frequent largish dots on them, which appear pale and pellucid, but sometimes dusky green; they are generally protuberant, and thereby render the surface irregular: the peduncles thick, herbaceous, bluntly triquetrous, from half an inch to an inch and half in length: the flowers rather large, like those of the Tongue-leaved sort, but somewhat smaller, and of a deeper yellow, internally of a shining golden colour, externally of a reddish saffron-colour, and when far advanced, saffron-coloured within. It is a native of the Cape.

The thirty-sixth species has the lower leaves oblique, the others more upright, not at all or but little bent in or sickle-shaped; they are long, thick, rigid, smooth and shining, flat within or on the top, underneath produced into a sharpish back, which becomes blunter and rounder in the lower part; all the sides are nearly equal: they are of a white elegantly glaucous colour, except that they are yellowish near the base with slender transverse lines: the flowers are large, yellow, on a long thick peduncle.

The thirty-seventh has the leaves in it as well as in all the varieties not decussated, but lying in the same oblique plane. It is a native of the Cape.

There are several varieties.

In the first, the leaves are wide and compressed about the edge: the flowers somewhat large, with blunt petals, scattered and not numerous, with scarcely any peduncle: one plant has several heads, from each of which are produced clusters of leaves in pairs, disposed like those of the Tongue Aloes, but with the edges not horizontal but oblique: there are generally three or four pairs of these leaves; they are broad and thick, flat above, pillowed below, bright green, smooth and shining, sometimes blunt, sometimes a little pointed, generally in the shape of a shoemaker's knife: the younger leaves in this and the other varieties are folded together and obliquely inserted into each other: the flowers come out successively in August and September from the axils, beginning with the lowest, they are subsessile, large, yellow, somewhat paler than in the following variety, shining in the sun: petals somewhat blunter, entire, or sometimes cut here and there.

The Broad Tongue-leaved variety has thick leaves, flat above, convex beneath, with the margins thicker and less upright than in the preceding, smooth and shining, pale green, especially toward the base, when held up to the light appearing to be composed of innumerable vesicles: three or four pairs of these leaves lie in the same inclined plane; these are sometimes flatter and blunt at the end, sometimes very much cut at the edge: from the lower pair first, and then from the next, a short peduncle arises, obtusely triquetrous, bearing a large flower of a shining golden colour, with many stamens, having oblong golden anthers.

The Narrow Tongue-leaved variety is very like the preceding, but the petals have a slight tinge of red on the outside: the older leaves are more reflex; the younger ones, which are closer and more luxuriant, are somewhat twisted in and excavated, and are of a fuller green colour: the fruit is smaller and softer, not elevated, but rather depressed, roundish, and commonly streaked with eleven angles; it is generally eleven-celled; the cells being the same in number as there are horns of the style, which are depressed at the bottom of the flower under the stamens, and are curled and wrinkled: the petals in two or three rows, almost of the same length, of a shining yellow colour. It flowers in August and September.

There is another variety, which is distinguished from the others by the leaves being longer and more erect: the peduncles of the flowers longer: the capsules less globular, commonly divided into nine cells: the calycine segments four, three longer and narrower, one shorter and broader,

with a membranaceous margin: the flowers have a double or triple row of petals, shining in the sun with the splendour of gold: the stamens numerous, with oblong saffron-coloured anthers.

The thirty-eighth species grows up into a stem an inch and more in thickness, and two or three feet in height, standing upright with little or no assistance, with a crown of clustered leaves a long span in length at the top, and branches a foot long and more at the base, which hang down with the weight of a multitude of leaves: very old plants grow a yard in height, with long incurved twisted branches: the stems and lower branches are of a dusky yellowish colour, but the upper flowering branches green; on the lower part of these the leaves are alternate, but on the upper part, where the flowers come out, clustered and somewhat shorter, in pairs at short intervals, triquetrous, with equal angles, slightly grooved on the sides, especially on the inner side; but the alternate ones have the inner side rather flat: they are not dotted, but are of a deep green, almost glaucous, like the leaves of Pinks, at the angles towards the base tinged slightly with purple: the peduncles from the axils of the upper leaves a span in length, thick, at first hanging down, but afterwards erect: the flowers large, expanding when the sun shines, straw-coloured above, tinged with red underneath, composed of numerous slender cuspid petals, gradually smaller, and the inner ones filamentose. The flowers are open from eight or nine in the morning to four or five in the afternoon. It is a native of the Cape, flowering from May to August.

The thirty-ninth has the stem short, thickish: the branches unequal, spreading irregularly on the ground, covered with a smooth bark of a dusky yellowish colour, with other smaller simple ones springing from them, which are also irregular and twisted: the leaves are pointed, slightly excavated within in the middle, the outer part produced and swelling, of a yellowish green colour, with frequent minute dots regularly in lines: the flowers are somewhat small, but white: the petals narrow, peduncles short, so that the flowers frequently scarcely emerge from the bundles of leaves: they are filamentose, and where white shine with a silvery brightness in the sun; but in the middle, next the stamens, are slightly tinged with yellow, and shine less: they are without scent, open two or three times, and in the day time only. It is a native of the Cape, flowering from June to October.

The fortieth has the stem shrubby, but procumbent; even when tied up its irregular twisted branches will hang down: they are round towards

the top, and of a yellowish bay colour, but quadrangular at the bottom: the leaves tender, mucronate, curved inwards, in bundles, acutely triangular, deep green and glaucous, having small dots and tubercles: the flowers are several, terminating, middle-sized, with scarcely any odour, on slender oblong peduncles: the calycine segments sometimes hooked, sometimes not: the petals very many, lying one over the other; the outer larger, bifid or trifid at the end; the inner ones gradually smaller, entire, but not filamentose: they are of a most vivid violet purple colour, but the flowers expand only about noon, when the sun is very hot: the flowers continue long, and open several times if the sun shines hot. It is a native of the Cape, flowering from June to August.

The forty-first species is from a foot and half to two feet in height: the stem not very shrubby, nor very thick: the branches woody, the thickness of a straw, procumbent, round, covered with an ash-coloured bark: the upper shoots of a yellowish bay colour, becoming pale herbaceous; they are gradually more slender, slightly compressed, and winged on each side with a process from the back of the leaves: the leaves difform; those which are fastened to the peduncles (bractes) short and thick, the others longer and not so thick, with other smaller leaves from the axils; all uncinat, subglaucous, rugged with frequent tubercles of the same colour, which when held up to the light appear to be so many porous dots: the flowers are on peduncles from an inch to two inches in length, alternately axillary, small, pale purple, petals twisted about, narrower towards the base, broader towards the end, entire, in a single row, smelling like those of the Hawthorn, open both day and night, for a long time, and in great abundance, there being a succession of them from July to October. It is native of the Cape.

Culture.—The annual and biennial sorts may be increased by sowing the seeds in the early spring months, on a fresh hot-bed, covered with sandy earth, or in pots of fine sandy mould.

When the plants have attained a few inches in growth, they should be planted on fresh hot-beds, or in pots plunged in them, to bring them forward; and when they have taken root, they should have very little water: when large enough, each should be planted in a small pot, filled with light fresh earth, but not rich, plunging them into a hot-bed of tan, shading them in the heat of the day until they have taken new root, when they should have plenty of fresh air. About the beginning of summer some of the plants may be injured

VOL. II.

to the open air, and afterwards be turned out of the pots, and planted with balls of earth about them in a warm border, where they often thrive and spread, but are not very productive of flowers in this way. Some must also be continued in pots, and removed to the shelves of the stove, where they flower more plentifully.

The culture which they afterwards require, is, for those in the pots to have frequent slight waterings in dry weather, and the others kept clean, and their branches permitted to spread upon the surface of the ground.

All the perennial sorts may be easily increased by cuttings planted during the summer months. Those having shrubby stalks and branches, readily take root when planted out in beds or in pots of light sandy soil, covered with mats or glasses: in the latter case, being shaded when the sun is warm. The cuttings of these sorts need not be cut from the plant more than five or six days before they are planted, during which time they should be laid in a dry room, not too much exposed to the sun, that the parts which were separated from the old plants may heal over and dry, otherwise they are apt to rot. They may then be planted at about three inches distance from each other, the earth being pressed very close to them, and none of their leaves buried in the ground, as from their abounding with moisture, when they are covered with the earth it is apt to cause them to rot, which often destroys the cuttings. When they are taken from the old plants, they should therefore be divested of their lower leaves, so as to allow a naked stalk of sufficient length for being planted in the earth.

Those in pots may be plunged in a hot-bed, or in a warm border, due shade and shelter being given, and slight waterings in dry weather. When they have stricken good roots, they should be removed with balls of earth into other separate small pots of light sandy mould, being placed in a shady situation, a very slight watering being given to settle the earth about them. After they become well rooted, they may be removed, so as to have more sun; when they may be kept till autumn, being watered very slightly twice a week in summer and once afterwards, care being taken to prevent their roots shooting through the pots, by shifting them two or three times in the summer, to pare them off.

In the autumn and winter they should be protected in the green-house.

The cuttings of the more succulent sorts should be left to heal over a much longer time, being a little freed from leaves, and covered with glasses to prevent the wet. They should have less water, and be removed less fre-

quently. They succeed well in an airy glass case during the winter, when screened from the frosts.

Such sorts as do not afford cuttings, may also be increased by planting and managing the bottom side-heads or off-sets in the above manner. They may likewise be increased by seeds or cuttings readily in the stove.

The only culture necessary afterwards is, only to give water frequently in small quantities in summer, and very sparingly in winter, shifting the plants occasionally into larger pots.

These are plants which afford a fine variety in green-house collections, and among other potted plants of similar growths.

MESPILUS, a genus containing plants of the deciduous tree, flowering shrubby, and evergreen kinds.

It belongs to the class and order *Icosandria Pentagynia*, and ranks in the natural order of *Pomaceae*.

The characters are : that the calyx is a one-leaved perianthium, concave-spreading, five-cleft, permanent; the corolla has five roundish concave petals inserted into the calyx : the stamina have twenty awl-shaped filaments, inserted into the calyx : anthers simple ; the pistillum is an inferior germ : styles five, simple, erect : stigmas headed : the pericarpium is a globular berry, umbilicated, closed by the converging calyx, but almost perforated by the navel : the seeds five, bony, gibbous.

The species cultivated are : 1. *M. Germanica*, Dutch or Common Medlar ; 2. *M. arbutifolia*, Arbutus-leaved Mespilus ; 3. *M. Amelanchier*, Alpine Mespilus ; 4. *M. Chamae-Mespilus*, Bastard Quince, or Mespilus ; 5. *M. Canadensis*, Snowy Mespilus ; 6. *M. cotoneaster*, Dwarf Mespilus ; 7. *M. tomentosa*, Quince-leaved Mespilus ; 8. *M. pyracantha*, Evergreen Thorn or Mespilus.

The first is a small or middle-sized branching tree : the branches woolly, armed in a wild state with stiff spines, covered with an ash-coloured bark : the leaves oval-lanceolate, serrate towards the point, somewhat woolly, on very short channelled petioles ; the bractes linear, as long as the corolla : the calyxes terminating, fleshy, woolly within ; teeth longer than the corolla : the petals white, blunt, entire, with a very short claw : the stamens unequal, thirty or more, with cloven anthers : the fruit an inferior turbinate berry, umbilicated at top with a wide depressed area, and crowned with the five linear calycine leaflets, fleshy, reddish brown ; pulp thick mixed with callose granules, containing five gibbous, wrinkled, one-celled stones, in each of which are two seeds.

It is observed that the wild tree differs from the cultivated one in having more slender, strigose, thorny branches, and much smaller leaves, flowers, and fruits. Pallas found all the parts very small, in his specimens from Persia, with narrower leaves, serrulate frequently almost to the base. In those from Caucasus the leaves were somewhat larger, and sometimes quite entire : and according to Gmelin, in the Persian Medlar, the leaves are red when they burst from the buds : the spines only three or four lines in length, stout, very sharp, spreading : the styles four or five : the fruit much smaller than in the garden sort. It is a native of the South of Europe, flowering in June and July.

There are two varieties, the narrow-leaved and the broad-leaved ; the first growing to a large tree, rising with a straighter stem, and the branches growing more upright than those of the Dutch Medlar : the leaves are narrower and not serrate : the flowers smaller ; and the fruit shaped like a pear. It is a native of Sicily.

The latter never rises with an upright trunk, but sends out crooked deformed branches at a small height from the ground : the leaves are very large, entire, and downy on their under side : the flowers very large, as also the fruit, which is rounder, and approaches nearer to the shape of an apple : this, bearing the largest fruit, is now generally cultivated ; but there is one with smaller fruit, called the Nottingham Medlar, of a much quicker and more poignant taste. There are also other varieties in the fruit, which are now little attended to.

The second species seldom rises more than five or six feet high, where it grows naturally ; and three or four feet is the greatest height it attains in this climate : the branches are few, slender, upright : the leaves alternate, pale green above, ash-coloured underneath : the flowers produced in small bunches, on long peduncles ; at the sides and extremities of the branches : the petals dull white, with several brown spots on their upper side : the fruit small, roundish, a little compressed, purple when ripe. It flowers in May, and the fruit ripens in October. It is a native of Virginia.

It varies with red, with black, and with white fruit.

The third rises with many slender stems three or four feet high, putting out small side branches covered with a dark purple bark : the leaves are three quarters of an inch long, and half an inch broad, slightly serrate : the small side branches, which sustain the flowers, are very hairy and woolly, as are also the footstalks and under side of the leaves, but their upper

sides are smooth and green: the flowers come out in bunches at the end of the shoots, are large and white: the petals are long and narrow, and the stamens about ten in number: the fruit small and sweet, black when ripe. According to Linnæus, while young the branches, petioles, peduncles and under surface of the leaves are tomentose; but when so far advanced as to bear fruit, it puts off the pubescence and becomes smooth. It is a native of the South of Europe.

The fourth species has a smooth stalk, about four or five feet high, sending out slender branches covered with a purplish bark: the leaves are about two inches long, and one inch and a half broad, yellowish green on both sides, on long slender foot-stalks: the flowers axillary, four or five together in a close head, purplish; with long, narrow, purplish bractes: the fruit small red. While young, it is also woolly, but when further advanced naked. It is a native of the Pyrenees, &c.

The fifth is a low shrub, seldom more than five feet high, dividing into several smooth branches, covered with a purplish bark: the leaves grow upon long slender foot-stalks; are an inch and a half long, and an inch broad, smooth on both sides, and serrate: the flowers come out in small bunches at the ends of the branches; are about the size of those of the common Hawthorn, and succeeded by small fruit of a purplish colour. It is a native of Canada and Virginia, flowering in April and May.

The sixth species is a low spreading shrub, not more than four or five feet high, covered with a smooth ash-coloured or purple bark, when young pubescent, but becoming smooth with age: the leaves alternate, the upper surface bright green and smooth, the lower white-tomentose, finely netted, about an inch long, and three quarters of an inch broad: the petioles two lines in length, channelled above: there are two lanceolate, acuminate, deciduous, reddish stipules at the base of the petioles: the peduncles either solitary and unbranched from the tops of the twigs, or forming little corymbs of three or four flowers, which are peduncled, somewhat-nodding, round and pubescent, with a small bract at the base. It is a native of many parts of Europe and Siberia, flowering in April and May.

The seventh has a smooth stalk about eight feet high, dividing into many smooth branches: the leaves are two inches and a half long, of a thick substance, dark green on their upper side, but downy on the under, standing upon short foot-stalks: the flowers come out of the side of the stalk, upon short small branches, five or six

growing upon each in a close bunch: the petals are of a purple colour, little longer than the calyx, which is woolly, with blunt segments: the fruit is large, roundish, and of a fine red colour when ripe. It flowers in April and May.

The eighth species is a bushy irregular shrub: the branches strigose and rugged, testaceous-brown, divaricated, alternately spinose: the spines are axillary, commonly branched with secondary spines, sometimes gemmiferous and producing branchlets: the leaves scattered, smooth, petioled, continuing till winter, lanceolate with a point, crenate; but in the garden serrate: the corymbs copious on the branches, compound, subsessile, or elevated on the leafy branchlets, on divaricating peduncles: the flowers white, scarcely larger than those of Elder: the berry globular, fulvous, the size of a pea, umbilicated with the calyx; pulpy and five-seeded. But according to Scopoli, the fruit is as large as the common Medlar; the seeds subovate and compressed. It is a native of the South of Europe, flowering in May.

Culture.—They are all easily raised by seeds, layers, grafting and budding; but it is the best practice to raise the Medlar kinds principally by grafting or budding, in order to continue the sorts. In the first method, the seeds should be sown in autumn, in a bed of common earth, as they usually lie a year, or more, before they germinate, as in the haw and holly-berries, &c.

When the plants appear they should be watered frequently in dry weather; and in the autumn or spring following, the largest be thinned out and planted in nursery-rows, two feet by one asunder; and in another year all the rest may be set out in the same manner; and in three or four years they will be proper for being planted out in the garden or shrubbery.

In the second mode the young branches should be laid down in the autumn in the common method; and they will be properly rooted by the autumn following, when they should be planted out in nursery-rows in the same way as the seedlings.

The two last methods should be performed on stalks of the larger Medlar kinds, or sometimes upon those of the White Thorn, raised from seed, as above; but the Pear-stock is to be preferred for the common Medlars, when intended as fruit-trees. The operations are performed in the usual way, low in the stocks to form dwarfs; and for half or full standards, training the first shoot for a stem, or the stock may be let form a stem, and then be wrought at from about three or four to five or six feet in height. See BODDING and GRAFTING.

Those intended for fruit-trees, whether dwarfs, half or full standards, in training, should,

for dwarfs, have the first shoots from the graft or bud headed down short in spring, if necessary, in order to force out a proper supply of bottom branches, which must be trained as other dwarf fruit-trees, either for standard-dwarfs or espaliers. When for half or full standards, and wrought low in the stock, the first shoot of each should be trained for a stem, topping it afterwards at the proper height to force out lateral shoots to form the head; but when wrought high in the stock, the first shoots may either be shortened or suffered to grow, as may seem most proper, according to the natural disposition of the leading shoot, in respect to its furnishing lateral branches. After this training for the first year or two, to give the trees their first proper formation, there should not be any further general shortening of the branches, practising it only occasionally to particular shoots, to procure more wood, when necessary, to fill vacancies, to reduce any irregular growth, or to cut off dead parts.

In other respects the branches should be principally left at full length, and the standards left to assume nearly their own natural way of branching. See PRUNING and TRAINING.

They are all hardy, succeeding in any common soil and situation.

The first sort and varieties are cultivated as fruit-trees, principally as standards, but sometimes as espaliers for variety; and are often introduced into the shrubbery plantations. All the other species are proper for ornament in shrubbery or other plantations, where they effect a fine variety, by their different foliage and flowers, as well as their fruit in autumn and winter, which remains long on the branches. They should be disposed—the deciduous kinds principally in assemblage with others of that sort, and the ever-green kind also chiefly with those of their own sort, arranging each sort according to its height of growth; but the last sort, being agreeably ornamental, both as an ever-green and in its numerous clusters of fine red berries in winter, should have a conspicuous situation. From its being of a rather slender growth, it is however commonly trained against walls or the fronts of houses, for the support of its flexible branches, as well as to exhibit its berries more ornamentally. It may however be trained as a standard shrub, like the other sorts, in the open shrubbery; in which case it should be generally trained with short single stems, and permitted to branch out upwards into spreading heads.

MESUA, a genus containing a plant of the exotic shrubby kind, for the hot-house.

It belongs to the class and order *Monadelphia Polyandria*, and ranks in the natural order of *Guttiferae*.

The characters are: that the calyx is a four-leaved perianthium: leaflets ovate, concave, blunt, permanent; the two outer smaller ones opposite: the corolla has four petals, retuse, waved: the stamina are numerous filaments, capillary, the length of the corolla, connate at the base into a pitcher: anthers ovate: the pistillum is a roundish germ: style cylindric: stigma thickish, concave: the pericarpium is a roundish nut, acuminate, with four longitudinal raised sutures: the seed single and roundish.

The species is *M. ferrea*, Ferreous Indian Mesua.

In its native situation it is a tree with opposite lanceolate leaves, five times as long as the internodes, quite entire, the upper surface smooth and green, the under glaucous and smooth; on very short petioles: the flower in each axil of the leaves sessile: the petal very large and rounded: the germ within the calyx: the style thick, the length of the stamens: the stigma capitate. According to Rheede, it is a very large tree, spreading like the lime, with flowers the size and shape of the wild rose or sweet brier, being much cultivated in Malabar for the beauty of the flowers, which come out there in July and August: and bearing smooth green fruit in six years from the nut. It is a native of the East Indies.

Culture.—This plant may be increased by seeds, layers, and cuttings.

The seeds should be sown in the spring, in pots of light earth, plunging them in a bark hot-bed in the stove. When the plants have attained some growth, they should be planted in separate pots and replunged in the bark-bed, where they must be kept.

The layers should be made from the young branches, and be laid down in the autumn or early spring, being taken off when well rooted, and planted in separate pots, having the same management as the others.

The cuttings should be taken from the young branches and be planted in the summer, in pots of light mould, and plunged in the bark-bed. When they have stricken root, they should be removed into separate pots, and be managed as the others.

They afford variety among other stove plants. MICHAUXIA, a genus containing a plant of the herbaceous, flowering, exotic kind.

It belongs to the class and order *Ocandria Monogynia*, and ranks in the natural order of *Campanaceae*.

The characters are: that the calyx is a one-

leafed perianthium, sixteen-parted: segments lanceolate, unequal, the alternate ones reversed: the corolla one-petalled, wheel-shaped, eight-parted, larger than the calyx: segments linear-lanceolate, spreading very much, revolute at the tip: nectary eight-valved, stamiferous: the stamina have eight awl-shaped, permanent filaments: anthers linear, very long, pressed close to the style: the pistillum is an inferior, turbinate germ: style columnar, permanent: stigma eight-parted: segments awl-shaped, revolute: the pericarpium is a turbinate capsule, truncated, eight-celled, valveless: cells rhomboid: the seeds very numerous, small, oblong, inserted into the receptacles.

The species is *M. campanuoides*, Rough-leaved Michauxia.

It is a handsome biennial plant: the stem simple, paniced when in flower, upright, herbaceous, rough-haired, green, two feet high, the thickness of the little finger, milky, as are also the branches, peduncles and calyxes: the branches alternate, axillary, flowering all over, spreading, reclining at the end: the root-leaves are petioled, cordate; the next petioled and runcinate: the stem-leaves half-embracing, lanceolate, acute, widening into ears at the base, irregularly gashed, serrate, nerved, wrinkled, rough-haired, rigid, waved, ascending at the sides, purple at the edge, four inches long, an inch and a half wide: the flowers are in a panicle, peduncled, bracted, hanging down, white, four inches in diameter: some slightly tinged with purple on the outside. It was found in the Levant.

Culture.—It may be raised from seed procured from its native situation and sown in the early spring season, in pots plunged in a hot-bed, or on a moderate hot-bed. When the plants have attained a little growth they should be removed into separate pots and be re-plunged in the hot-bed. It must afterwards be managed as tender green-house plants.

It affords variety in collections of this sort.

MICHELIA, a genus containing a plant of the tree or shrub kind.

It belongs to the class and order *Polyandria Polygynia*, and ranks in the natural order of *Coarctatae*.

The characters are: that the calyx is a three-leaved perianthium: leaflets petal-form, oblong, concave, deciduous: the corolla has fifteen petals, lanceolate; the outer ones larger: the stamina have very many awl-shaped filaments, very short: anthers erect, acute: the pistillum has numerous germs, imbricate in a long spike: styles none: stigmas reflex, blunt: the pericarpium berries (berried capsules) as many,

globular, one-celled, half-bivalved, dispersed in a raceme: the seeds four, (from two to eight,) convex on one side, angular on the other.

The species is *M. Champaca*, Champaca or Indian Michelia.

In its native situation it is a lofty tree, with a trunk as large as a man can compass, covered with a thick ash-coloured bark, but in this climate it is only the size of a shrub: the leaves are a span or more in length, and four or five inches in width, contracted into an oblong narrow point, of a hard texture, flat and smooth, dusky green above, brighter green beneath, on petioles an inch in length: the flowers on the extreme twigs, axillary, on thick, upright peduncles an inch and a half in length, and having a very fragrant smell: the petals narrow, in three rows; in the outer row eight, three times as broad as those in the middle row, which are also eight; towards the top they are more round and sometimes pointed or cusped, but less so than in the middle row: in the inner row they are small, short, very much cusped towards the top, pale yellow: fruit oblong spheroidal, with a thickish rind, first green, then pale whitish yellow, having a very sharp taste, and not very pleasant smell. It is a native of the East Indies.

Culture.—This plant may be increased by seeds, layers, and cuttings, managed in the same manner as the above sort.

It affords variety in collections of stove plants.

MILFOIL. See ACHILLEA.

MICE, a sort of vermin highly destructive to several sorts of garden crops, such as peas and beans in the early spring, and lettuces, melons and cucumbers in frames in the winter season. When discovered they should be immediately destroyed. See VERMIN.

MILDEW, a vegetable disease very hurtful to some kinds of plants. It is supposed to proceed from different causes: some consider it as a kind of thick clammy moisture, which falls on, or rather transpires from, the leaves and blossoms of plants, which, by stopping up the pores, prevents perspiration, and hinders their growth. The author of *The Philosophy of Gardening* suspects it to be a plant of the fungous kind, which grows without light or change of air, and with its roots penetrates the vessels of the vegetables to which it adheres, which are probably previously diseased, and thus deprives them of their due nourishment. But what is commonly denominated mildew is an insect which is frequently found in vast numbers feeding upon the effused moisture. In a treatise upon this

disease by Mr. Segar, it is conceived to be of a very sharp corrosive nature, and by its acrimony to hinder the circulation of the nutritious sap; in consequence of which the leaves begin to fade, and the blossoms and fruit to be greatly injured.

The author first mentioned conceives the best method of removing it to be by admitting more light and air, by proper thinning or pruning so as to restore the natural vigour of the plants.

Mr. Forsyth has observed that, "contrary to the common opinion, trees are more liable to mildew on south and west walls, than on an east wall; and has frequently removed such trees from a south or west wall, to a north or east wall, where they have perfectly recovered.

He advises "whenever danger is apprehended, to wash or sprinkle the trees well with urine and lime-water mixed; and when the young and tender shoots are much infected, to wash them well with a woollen cloth dipped in the following mixture, so as to clear them of all the glutinous matter, that their respiration and perspiration may not be obstructed.

"Take of tobacco one pound, sulphur two pounds, unslaked lime one peck, and about a pound of elder-buds; pour on them ten gallons of boiling water; cover it close and let it stand till cold; then add as much cold water as will fill a hogshhead. It should stand two or three days to settle, when the scum may be taken off, and it is fit for use.

"There is a sweet saccharine substance found on the leaves of certain trees, which is generally but erroneously supposed to fall from heaven like dew. It is known by the title of *Honey-dew*. There are supposed to be two kinds of it, one of which Mr. Forsyth says "transpires from the leaves of the trees where it is found; and the other is the excrement of a small insect called a Vine-fretter, a species of the Aphis. Bees and ants are very fond of both these kinds of honey-dew." As this exudation, "by its viscous quality," closes up the pores and stops the perspiration of trees, it must of course," he thinks, "be very hurtful to them."

It is a vegetable disease, which should, in his opinion, be treated in the same manner as the mildew, by washing at the same times.

MIMOSA, a genus containing plants of the shrubby and under shrubby kind.

It belongs to the class and order *Polygamia Monœcia* and ranks in the natural order of *Leguminosæ*.

The characters are: that the calyx is a one-leaved perianthium, five-toothed, very small:

the corolla has one petal, funnel-form, half-five-cleft, small: the stamina have capillary, very long filaments: anthers incumbent: the pistillum is an oblong germ: style filiform, shorter than the stamens: stigma truncated: the pericarpium is a long legume, with several transverse partitions: the seeds many, roundish, of various forms.

The species cultivated are: 1. *M. plena*, Double-flowered Annual Sensitive Mimosa; 2. *M. viva*, Lively Mimosa; 3. *M. quadrivalvis*, Quadrivalve-podded Humble Mimosa; 4. *M. sensitiva*, Sensitive Plant; 5. *M. pudica*, Humble Plant; 6. *M. virgata*, Long-twiggèd Mimosa; 7. *M. punctata*, Spotted-stalked Mimosa; 8. *M. pernambucana*, Slothful Mimosa; 9. *M. asperata*, Hairy-podded Mimosa; 10. *M. pigra*, Slow American Sensitive Plant; 11. *M. glauca*, Glaucous Mimosa; 12. *M. cornigera*, Horned Mimosa, or Cuckold Tree; 13. *M. horrida*, Horrid Mimosa; 14. *M. Farnesiana*, Farnesian Mimosa, or Sponge Tree; 15. *M. Nilotica*, Egyptian Mimosa; 16. *M. verticillata*, Whorl-leaved Mimosa; 17. *M. arborea*, Rough Tree Mimosa; 18. *M. Lebbeck*, Lebbeck, or Egyptian Mimosa; 19. *M. latisiliqua*, Broad-podded Mimosa; 20. *M. tamarindifolia*, Tamarind-leaved American Mimosa; 21. *M. circinalis*, Spiral Mimosa; 22. *M. pennata*, Small-leaved Mimosa; 23. *M. latifolia*, Broad-leaved Mimosa; 24. *M. purpurea*, Purple Mimosa, or Soldier Wood; 25. *M. reticulata*, Netted Mimosa; 26. *M. scandens*, Climbing Mimosa; 27. *M. myrtifolia*, Myrtle-leaved Mimosa; 28. *M. suaveolens*, Sweet-scented Mimosa.

The first, when cultivated in the garden, has great resemblance to the seventh sort; but the stalks never grow so erect, the wings of the leaves are longer, and stand more horizontal: the heads of flowers are much larger, the stamens are longer, and the flowers on the under side of the spike which have no stamens are double; the pods also are shorter, and much broader than those of that sort.

It is annual; the stems round, herbaceous, smooth, procumbent, rooting at all the joints: the leaves three-paired or four-paired, contracting with the least touch: from the axils of these spring erect peduncles, four or five inches high, with scales the whole length, sustaining handsome, yellow, almost globular heads, the same size with those of red clover: the flowers different in shape, nature and use; those in the middle truly five-petalled, in small five-cleft calyxes, with many long stamens; but those in the circuit, instead of stamens have oblong, beautiful, golden leaflets, much wider and handsomer than the true petals, which are small

and of a greenish colour. These double flowers are barren; but the single ones are succeeded by flat, smooth, two-valved legumes, containing several black, shining, compressed seeds. It is a native of La Vera Cruz.

The second species has trailing herbaceous stalks, putting out roots at every joint, and spreading to a considerable distance: A single plant, in the stove, in one summer, has spread near three feet square, and the branches so closely joined, as to cover the surface of the bed; but when permitted to grow thus, the plants seldom produce flowers: the leaflets are narrow, and the petioles are short and smooth: the flowers axillary, on naked peduncles about an inch in length; they are of a pale yellowish colour, and are collected into small globular heads: the legumes short, flat, jointed, containing three or four compressed, roundish seeds. It is a native of Jamaica.

The third has a creeping root: the stalks slender, having four acute angles, armed pretty closely with short recurved spines: the leaves on long prickly foot-stalks, and thinly placed on the branches: the wings two pairs, about an inch asunder, short: the leaflets narrow, not very close: the peduncles axillary, sustaining a small globular head of purple flowers: the legumes four-cornered, two inches long, four-celled, four-valved; containing several angular seeds in each cell. It was found at La Vera Cruz.

The fourth species rises with a slender woody stalk, seven or eight feet high, armed with short recurved thorns: the leaves grow upon long foot-stalks which are prickly, each sustaining two pairs of wings; the outer pair has two lobes which join at their base, and are rounded on the outside, but straight on the inner edges, shaped like a pair of sheep-shears; they are much larger than the inner, are almost two inches long, and one inch broad in the middle: from the place where these are inserted into the stalk, come out small branches, which have three or four globular heads of pale purplish flowers coming out from the side, on short peduncles; and the principal stalk has many of those heads of flowers on the upper part for more than a foot in length; and this, as also the branches, is terminated by similar heads of flowers: the pods are broad, flat, jointed, opening by two valves, containing one, two, or three compressed orbicular seeds: the leaves move but slowly when touched, but the foot-stalks fall when they are pressed very hard. It is a native of Brazil.

The fifth has the roots composed of many hairy fibres, which sit close together, from

which come out several woody stalks, which decline towards the ground, unless they are supported; they are armed with short recurved spines, and have winged or pinnate leaves, composed of four, and sometimes five pinnae, whose bases join at a point, where they are inserted into the foot-stalk, spreading upwards like the fingers of a hand: the flowers from the axils, on short peduncles, collected in small globular heads, of a yellow colour: the pods short, flat, jointed, in close clusters, almost covered with stinging hairy covers. It is a native of Brazil.

The sixth species has the spike roundish, nodding: the flowers ten-stamened, and yellow; the lower ones of the spike without stamens or petals. It is a native of the West Indies, flowering in July and August.

The seventh rises with upright branching stalks six or seven feet high, becoming woody towards the root, with callous dots dispersed upon it, but not perennial (at least they are not so here in any situation, the plants always decaying in winter); they are smooth, and the leaves are composed of four or five pairs of long winged lobes, which have about twenty pairs of small leaves ranged along the midrib; are smooth and rounded at their points, of a full green on their upper side, but pale on their under: these small leaves contract themselves together on their being touched, but the foot-stalks do not decline at the same time, as those do which are titled Humble Plants: it is therefore called the Sensitive Plant by way of distinction: the flowers are produced upon long foot-stalks, which come out from the wings of the leaves, and are disposed in globular heads which nod downward, are yellow; and all those which have petals have ten stamens in each, but those situated round the border have neither petals nor stamens; those on the upper part of the spike are succeeded by pods an inch and a half long, and a quarter of an inch broad, which change to a dark brown when ripe, inclosing three or four compressed, shining, black seeds. It is probably a native of America.

The eighth species has the stems seldom more than two feet and a half high, and smooth: the leaves are composed of three or four pinnae, which are shorter, and the leaflets much narrower than in the first and seventh sorts: the heads of the flowers are smaller, being made up of many long white filaments, forming altogether a round head, and the pods longer and narrower, an inch long, and a quarter of an inch broad, with a round protuberance at each seed. It grows naturally in all the islands of the West Indies, where it has its name from the leaves not contracting on being touched.

The ninth species has a shrubby erect stalk about five feet high, hairy and armed with short, broad, strong thorns, which are white, standing on each side, almost opposite, or alternate: the leaves five- or six-paired, with a strong midrib, and between each pair two short strong spines, pointing out each way: the leaflets extremely narrow and very close: towards the upper part of the stalk the flowers are produced from the sides on short peduncles; they are collected into globular heads, and are of a bright purple colour: the stalks are also terminated by smaller heads of the like flowers: the pods flat, jointed, about two inches long, and a quarter of an inch broad, spreading like rays, there being commonly five or six joined together at the base: they separate at each articulation, leaving the two side membranes or borders standing: the seeds, which are compressed and square, drop out from the joints of the pods, which are hairy at first, but as they ripen become smooth: the petioles do not fall on being touched, but the leaflets close up. It is a native of La Vera Cruz.

The tenth has the stem recurved, prickles scattered over it in pairs: the leaves commonly six-paired, with many paired pinnae: on the universal petioles there are recurved prickles between each of the partial ones; and there is a straight upright prickle which is longer, between each pair of the partial ones, in place of a gland: the heads are globular: the legumes membranaceous-compressed, jointed, rugged. It is a native of South America.

The eleventh species has the spikes globular, large, peduncled: the flowers white, apetalous, ten-stamened: the legumes long, flat. It flowers in April, and the seeds ripen in autumn; found at La Vera Cruz.

The twelfth is a tree which seldom exceeds twelve feet in height: it has numerous branches forming a pyramidal figure: the leaves are small; the flowers are small, yellow, and void of scent, in a close cylindrical spike, an inch and a half long: the legumes coriaceous, containing a buttery pulp, in which the seeds are rolled up: the spines are very singular, subaxillary and connate at the base, resembling the horns of oxen; brown, shining, hollow, and the longest more than five inches in length; they are all over the tree; and when the pods are ripe and the leaves fallen, they have a singular appearance. It is a native of Carthage, flowering in June and July, and ripening seeds in September.

The thirteenth species has the branches angular, smooth, with a brown bark: the leaves sometimes two from the axil of the spines: partial four- or five-paired, inner shorter, with

leaflets from five- to seven-paired, outer eight- to eleven-paired: leaflets linear, acute, smooth: the spines in pairs white, purple at the tip: the flowers in a globular head, axillary and solitary, first sessile, then peduncled, shorter than the leaves: the legumes compressed, and attenuated at the base. It is a native of the East and West Indies, &c.

The fourteenth has the flowers many-stamened, very fragrant, yellow, in sessile heads: the petioles have a gland below the leaflets: the legumes are fusiform. On account of the sweetness of its flowers, it has been dispersed through most parts of Europe. It is brought by the Italian gardeners, who bring over Orange-trees, &c. in young plants, under the name of *Gazia*. It is a native of Saint Domingo, flowering from June to August.

The fifteenth species is a tree which arrives at a large size in countries where it grows naturally, but in this climate is rarely seen more than eight or ten feet high: it has the habit of the fourteenth sort; differing in having no callous dots upon the branches: the bark is purple: the spines in pairs, and longer than those of the fourteenth: the branches purple, even: the partial leaves about five pairs; between two pairs of the outer ones a gland is inserted into the common petiole: the legumes necklace-shaped, compressed: the joints roundish-rhomb-shaped: flowers many-stamened, in peduncled heads. It is a native of Egypt and Arabia. It is the tree which yields the Gum Arabic.

The sixteenth has leaves simple, linear, and pungent or hard and prickly at the end, and growing in whorls six or seven together; but it has dissimilar leaves, and the primordial ones, or two or three first leaves which appear on the seedling plants, are bipinnate. It is a native of New South Wales, flowering from March to May.

According to Mr. Curtis, it is some years in arriving at its flowering state.

The seventeenth is a lofty tree, with an upright smooth trunk, covered with an ash-coloured bark: the branches diverging, bent down, smooth: the partial leaves twelve-paired: the universal petiole round, striated, ferruginous-pubescent: partial petioles also ferruginous: the glands roundish, concave, between the petioles: the scalelets bifid, minute, at the base of the partial petioles: pinnae sixteen- or eighteen-paired, halved, subsessile, acute, entire, smooth: the spikes peduncled, subglobular, composed of aggregate, sessile, white flowers: the peduncles axillary, and slender: the seeds spherical, shining black. It is a native of Jamaica, where it is called *Mountain or Wild Tamarind Tree*.

The eighteenth has the leaves destitute of glands : the pinnae from twelve to twenty, an inch in length : the bundles of flowers peduncled : the legume a span long. It is cultivated in the gardens at Cairo, where it flowers in June, and becomes a large tree. It is probably a native of Egypt.

The nineteenth has the bractæ half-cordate : the peduncles in threes : the flowers in heads : an obsolete gland on the common petiole below the partial pinnae : the germs are globular, two-valved ; with two roundish, concave or hemispherical leaflets : the leaves very smooth. It is a native of the West Indies, flowering most part of the summer.

The twentieth species has the branches with few recurved prickles : the leaves four- or five-paired : a gland between the lowest partial ones, which are twelve-paired, but the lowest pinnule wants the opposite on the inside : on the common petiole are two remote prickles, underneath between each partial one : the stipules wide, acuminate, purple : the legumes very wide. It is a native of America.

In the twenty-first, the leaves divide into many ramifications : the leaflets are roundish, and placed in a very regular order : the seeds, which are flat, and one half of a beautiful red colour, the other half of a deep black, grow in long twisted pods, and hanging by a small thread for some time out of the pod, when they are ripe, make a very agreeable appearance. It was brought from the Bahama Islands.

The twenty-second species is frutescent, being a large procumbent branching shrub : the panicle very much branched, naked, terminating the stem and branches : the prickles small, scattered over the stem and panicle : the leaves having from twelve to twenty pairs of partial leaves, with an oblong melliferous pore at the base of the general petiole : the leaflets linear and almost capillary : there are no prickles on the petioles or peduncles, but a gland above the base of the petioles : the flowers white, polygamous, in a vast diffused terminating panicle, of very many small globular heads. It is a native of the East Indies.

The bark is there converted into a sort of tow, which is used for stopping cracks both in houses and boats.

The twenty-third sort has the flowers many-stamened, sessile : the leaves are like those of the Walnut ; and the flowers are purple. It is a native of South America.

The twenty-fourth has also purple flowers, and is a native of South America.

The twenty-fifth is a tree with rigid branches, that are flexuose from bud to bud : under each

bud is a pair of horizontal, whitish, stipular thorns, the length of the leaves : the leaves are petioled, conjugate, or one-paired, with pinnate, six-paired leaflets : the common petiole terminated above by a gland, beneath by a prickle : the leaflets oblong-linear, blunt, at equal distances, the lowest smaller : the legume oval, a hand in length and half as much in breadth, compressed, with large scattered seeds. It is a native of the Cape.

The twenty-sixth climbs to the tops of the tallest trees, to the height of one hundred and fifty feet, frequently overspreading many of the neighbouring branches, and forming large arbours : the withs are slender, but tough and flexile, striated, stiff, and smooth : common petioles long, opposite, thickened at the base, round, very smooth, terminating in a tendril, by which the branches are supported : the pinnae four-paired, petioled, oblong, blunt at top, emarginate, nerved, smooth on both sides, shining : the glands none : the tendril long, upright, bifid at the end : the spikes axillary, erect, very long, many-flowered : the flowers approximating, subsessile, small : most of them are abortive : and according to Browne, the female plants throw out their flowers separate, and are succeeded by so many pods. It is a native of both Indies, and in the West Indies is called *Cocoon*.

The twenty-seventh species is in height three or four feet : the branches alternate, upright, angular, with a very tough smooth bark : the leaves of the young seedlings in pairs and pinnate, with oval leaflets : but when the stem rises, the common footstalks of its leaves become dilated, the leaflets cease to appear, and the whole shrub is furnished only with such dilated naked footstalks, which are to all intents and purposes leaves. They are alternate, vertical, smooth, firm and glaucous : the stipules none : on their upper edge near the base a small concave gland : the racemes are axillary, solitary, erect, of about six alternate heads, each having three or four small white flowers : the pod linear, pointed, zigzag, brown, with a very thick margin : the seeds about six, oblong : the flowers on the young branches are very numerous, and fragrant, like those of *Spiræa Ulmaria*. It is a native of New South Wales.

It produces ripe pods, and perfects seeds in the stove, but in the green-house the flowers go off without any tendency to produce fruit. It is a shrub of quick growth, and which blows very readily.

According to Mr. Curtis, the foliage is usually edged with red.

In the twenty-eighth the branches are most

acutely triangular, and much compressed; their edges bright red: the leaves alternate, four or five inches long, with a rib and margin like the last: the flowers in axillary racemes, yellowish white, fragrant: the petals four: stamens numerous: the young capsules smooth and glaucous. It is a native of New South Wales.

Culture.—They are all capable of being increased by seed, and some of the sensitive kinds by layers and cuttings, but the first is by much the best method.

The seed, procured from the nurseries or seed-shops, should be sown in pots of light rich mould early in the spring, covering it in with fine earth a quarter of an inch deep, and plunging the pots in the hot-bed; if in a common hot-bed under frames and glasses, managing them nearly in the manner of tender annuals, and when in a bark-bed in the stove, little trouble is required. But moderate sprinklings of water should be given; and when the plants are two or three inches high, they should be planted out singly into small pots, preserving the earth to their roots, replunging them in the hot-bed, &c., giving water and occasional shade till they are well rooted, repeating the waterings frequently. The plants should afterwards be continued either in the hot-bed under glasses, or plunged in the bark-bed of the stove, to facilitate their growth, preserve them in vigour, and increase the sensibility of the Sensitive kinds; admitting fresh air pretty freely.

The perennial sorts, both shrubby and herbaceous, must be kept in the stove all winter, and principally the year round.

And they must be frequently removed into larger pots to prevent the roots from getting through the pots, which they are apt to do, and by that means are often destroyed.

The *Acacia* kinds are the most tender, requiring the stove almost constantly, except a little in the heat of summer, when they must be placed in a warm situation.

They should always have a bark hot-bed, and be put in very small pots filled with sandy mould, the heat of the stove being kept up to above temperature as the leaves of some of them are shed, they have often the appearance of being dried when that is not the case.

Where there is not the convenience of a stove, those who are curious to have the plants, may have them in summer, by the aid of a common dung or tan-bark hot-bed under frames and glasses, though not in winter; by raising some of the annual, or any of the other kinds, by seed in spring, in a hot-bed under a frame, &c. keeping up the heat of the bed until the middle of June, and continuing the plants always un-

der the frame, raising one end of the lights a little, occasionally, in warm days to admit fresh air; and as they rise in height, raise the frame at bottom, to allow them full room to grow. About Midsummer, or soon after, some of the low spreading kinds may likewise be turned out with balls, or plunged in their pots into a warm sunny border, and covered with large hand-glasses, which may be lifted off occasionally just to view the plants. By these methods the plants may be preserved through the summer in their sensitive quality, though not equal in perfection to those in stoves; nor can they be preserved alive in winter out of the stove.

The shrubby kinds that afford spreading branches may be layed any time in summer, in pots plunged in the bark-bed, where they then take root, and are ready to pot off singly in the autumn season.

The Sensitive and Humble sorts often branch out profusely, so as to furnish plenty of young shoots for cuttings, which should be planted in pots in the summer season, plunging them in the bark-bed, where they often readily take root, and form good plants.

These modes should, however, only be practised when seed cannot be procured.

The general culture of all the species is afterwards to keep them always in pots placed in the stove, being plunged occasionally in the bark-bed, especially the Spreading Sensitive kinds, frequent waterings being given in summer and winter, but considerably the most in the summer season; shifting them into larger pots as they increase in growth. And although most of the sorts will live in the open air in the heat of summer, it is the best practice to expose them but sparingly.

The fourth and fifth sorts are held in high estimation on account of the singular sensibility lodged in their leaves; which, in consequence of being touched or shaken, either by the hand, a stick, or the least wind blowing upon them, the wings of the leaves suddenly close, and the foot-stalks fall down.

The periods of time which the leaves, &c. require to recover themselves, after falling from any irritation, are according to the vigour of the plant, the hour of the day, the serenity of the atmosphere, and the temperature of the heat of the stove, &c. being often from ten or fifteen minutes to an hour or more.

The plants also every evening naturally contract themselves, and expand again in the morning. They are all ornamental and curious.

MIMULUS, a genus containing a plant of the herbaceous flowery ornamental kind.

It belongs to the class and order *Didynamia*

Painted by Val. Edwards
Mirabilis jalapa
 'Marvel' of Peru.

London Published Mar 1180 by G. Knapp, Fleet Street
 2 *Mimosa sensitiva*
 Sensitive Plant.

Engraved by F. Sanfey
 3 *Monarda didyma*
 Scarlet Monarda.

Angiospermia, and ranks in the natural order of *Personatæ*.

The characters are: that the calyx is a one-leafed perianthium, oblong, prismatic, five-cornered, five-folded, five-toothed, equal, permanent: the corolla is one-petalled, ringent: tube the length of the calyx: border two-lipped: upper lip upright, bifid, rounded, bent back at the sides: lower lip wider, trifid, with the segments rounded; the middle one smaller: palate convex, bifid, protruded from the base of the lip: the stamina have four filaments, filiform, within the throat; two shorter: anthers bifid-kidney-form: the pistillum is a conical germ: style filiform, the length of the stamens: stigma ovate, bifid, compressed: the pericarpium is an oval, two-celled capsule, opening transversely at top: partition membranaceous, contrary to the valves: the seeds very many, and small: the receptacle oblong, fastened on each side to the partition.

The species cultivated are: 1. *M. ringens*, Oblong-leaved Monkey-flower; 2. *M. alatus*, Wing-stalked Mimulus; 3. *M. aurantiacus*, Orange Monkey-flower.

The first has a perennial root: the stalk is annual, square, a foot and half high, with two oblong smooth leaves at each joint, broadest at their base, where they join round the stalk, but ending in acute points: the lower part of the stalk sends out two or three short branches, and the upper part is adorned with two flowers at each point, from the bosom of the leaves on each side; they are of a violet colour, and have no scent. It is a native of Virginia and Canada, flowering in July and August.

The second species has the appearance of the first sort: the stem is winged with four membranes running down from the base of the petioles, simple, smooth, with a branchlet or two at top: the leaves are two inches long, veined, unequally serrate: the peduncles axillary, solitary, opposite, four-cornered, thickened at top. It is a native of North America, flowering in July and August.

The third has the stalk about three feet high, much branched, shrubby, round, the young wood green, with a tinge of purple towards the lower part of each joint, slightly viscid, as it becomes older changing to a light-brown colour, and discovering manifest fissures: the branches alternately opposite, flower-bearing quite to the base: the leaves are opposite, sessile, slightly connate, the bluntness at the end particularly apparent when contrasted with a leaf of the first sort, toothed or slightly serrate, smooth, veiny: the flowers inodorous, large, nearly twice the size of those of the first sort, uniformly pale orange, growing in pairs from the axils of the

leaves, on peduncles that are about half the length of the calyx. It flowers during most of the summer.

Culture.—This plant is very hardy in respect to cold, but should have a loamy soft soil, rather moist than dry, and not too much exposed to the sun.

The first sort may be increased by parting the roots not too small, and planting them in autumn, or the early spring, but the former is the better season. It may also be raised by seeds, which should be sown in autumn, soon after they become perfectly ripe, on a border exposed to the morning sun.

The third sort may likewise be increased in the same manner.

The fourth kind is best propagated by planting cuttings of the young shoots or branches in the early spring in pots of fresh mould, plunging them in a mild hot-bed, being afterwards managed as the other sorts.

The first is capable of bearing cold when planted in a loamy, soft, rather moist soil, not too much exposed to the sun.

This and the second sort may be introduced in the borders and clumps, and the third among other potted plants of the less tender kinds.

MINT. See MENTHA.

MIRABILIS, a genus furnishing plants of the flowery perennial kind.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Nyctagines*.

The characters are: that the calyx has the outer perianthium one-leafed, erect-ventricose, inferior, five-parted: segments ovate-lanceolate, sharp, unequal, permanent: inner globular placed under the petal, with a contracted entire mouth, and permanent: the corolla is one-petalled, funnel-form: the tube slender, long, thicker at top, placed on the inner calyx: border from upright spreading, entire, bluntly five-cleft, plaited: nectary spherical, fleshy, surrounding the germ, with a five-toothed mouth: teeth very small, triangular, converging: the stamina have five filaments inserted into the orifice of the nectary, and alternate with its teeth, within the inner calyx free, more slender, fastened at bottom to the tube of the corolla, filiform, the length of the corolla, inclining, unequal: anthers twin, roundish, rising: the pistillum is a turbinate germ, within the nectary: style filiform, the length and situation of the stamens: stigma globular, dotted, rising: there is no pericarpium: the inner calyx incrusts the seed and falls with it: the seed single, ovate-five-cornered.

The species cultivated are: 1. *M. jalapa*, Common Marvel of Peru; 2. *M. dichotoma*,

Forked Marvel of Peru; 3. *M. longiflora*, Sweet-scented Marvel of Peru.

The first has a thick fleshy root: the stem thick, upright, much branched, and divided three feet or more in height: the leaves are broad, oblong, and opposite: flowers terminating, about six, in clusters close together without any leaflets between them, and not longer than the leaf. It is perennial, and a native of both the Indies, flowering from July to October.

There are several varieties in the colour of the flowers, as purple or red, white, yellow, variegated purple and white, and variegated purple and yellow, but which resolve themselves into two principal varieties; as with purple and white flowers, which are variable; some being plain purple, others plain white, but most of them variegated with the two colours, and all found occasionally on the same plant; and with red and yellow flowers, generally mixed, but sometimes distinct on the same plant; some plants having only plain flowers, others only variegated, and others again both plain and variegated: but the plants which are raised from seeds of the purple and white never produce red and yellow flowers, or the contrary.

All these varieties are highly ornamental during the months of July, August, and September, and, when the season continues mild, often last till near the end of October. The flowers opening only towards the evening, while the weather continues warm, but in moderate cool weather, when the sun is obscured, they continue open almost the whole day, and are produced so plentifully at the ends of the branches, that when expanded the plants seem entirely covered with them, and from some being plain, others variegated, on the same plant, have a fine appearance.

The second species resembles the first sort very much: the stalks have thick swollen joints: the leaves are smaller: the flowers not much more than half the size, and do not vary in their colour from their natural purplish red: the fruit is very rough. It is a native of Mexico; and common in the West Indies, where it is termed the *Four o'Clock Flower*, from the circumstance of the flowers opening at that time of the day.

In the third, the stalks fall on the ground, if not supported; they grow about three feet in length, and divide into several branches; are hairy and clammy: the flowers come out at the ends of the branches, are white, have very long slender tubes, and a faint musky odour, as in the other sorts; are shut during the day, and expand as the sun declines: the seeds are larger than those of the other species, and as rough as those of the second sort. It is a native of Mexico, flowering from June till September.

Culture.—In all the sorts the propagation is effected by sowing the seed in the spring season, either on a warm border or in a hot-bed; but the latter method produces the plants considerably more early, and in the greatest perfection.

When cultivated on warm south borders, in the places where the plants are to remain, the seed should be sown about the middle of April, either in patches or in shallow drills, half an inch deep, and six inches asunder: and when the places can be covered with hand-glasses, or a frame and lights, or the seed be sown in pots under those protections, or any other occasional shelter during the night-time and in cold weather, it will greatly forward the germination of the seed, as well as the growth of the young plants afterwards. In the latter method, about June, the plants will be fit to plant out into the borders or into pots. Moist weather should be chosen for this purpose, and water and occasional shade be given till well rooted: they then readily grow, and acquire a tolerable size; but they do not attain to a large size, or flower so early by a month or six weeks as those forwarded in the hot-bed.

In the latter method, a hot-bed should be prepared in March, or early in April, under frame and lights, and earthed over about six inches deep; then sowing the seed in the earth of the bed in shallow drills half an inch deep, as directed above, or in pots of rich earth the same depth, plunging them in the earth of the bed. The latter is the better method. The plants soon rise; when they should have fresh air daily, in common with the other plants of the bed, and frequent refreshings of water; and when nearly two inches high, be planted out into another fresh hot-bed to forward them, placing them either in the earth of the bed, four or five inches asunder, or singly in small pots (thirty-twos), plunging them in the bed; water and shade should be immediately given till fresh-rooted, continuing the care of admitting fresh air every mild day; and about the middle or latter end of May, when they have acquired a good size and strength, they should be inured by degrees to the full air, so as that they may be removed into it fully about the beginning of June, choosing mild cloudy moist weather, if possible, for the business; taking up such as grow in the beds, with balls of earth about their roots, and planting them in the borders; but those in pots may be turned out with the whole ball entire, and planted in that way. Some should also be removed into large pots for moving into particular situations. Water should be directly given, and occasional shade to such as

require it, repeating the waterings to the whole, till they have struck fresh root and begun to grow, when they will not require any further culture, except the occasional support of sticks, which is most necessary in the last sort.

As the seed ripens well, it will frequently prevent the trouble of preserving the roots.

But when these are taken out of the ground in autumn, and laid in dry sand during the winter, secure from frost, and planted again in the spring, they grow much larger and flower earlier than the seedling plants: or when the roots are covered in winter with tanner's bark to keep out the frost, they often remain secure in the borders, where the soil is dry. When the roots thus taken out of the ground are planted the following spring in large pots, and plunged into a hot-bed, under a deep frame, they may be brought forward, and raised to the height of four or five feet, and flower much earlier in the season.

In collecting the seeds, care should be taken not to save any from the plants which have plain flowers; and in order to have variegated flowers, the plain flowers should be pulled off from those plants which are intended to stand for seed.

As the second sort is less hardy than the first and third, unless the plants are brought forward in the spring they seldom flower till very late, and their seeds do not ripen perfectly.

All the sorts are proper for the principal borders of pleasure-grounds, being very ornamental in their large branchy growth, as well as in their extensive flowering.

The root of all the sorts is a strong purgative.

MOLUCCA BAUM. See **MOLUCCELLA**.

MOLUCCELLA, a genus containing plants of the herbaceous annual exotic kind.

It belongs to the class and order *Didynamia Gymnospermia*, and ranks in the natural order of *Verticillatae*.

The characters are: that the calyx is a one-leaved perianthium, very large, turbinate, gradually finishing in a very wide, bell-shaped, tooth-spiny, incurved, permanent border: the corolla is one-petalled, ringent, less than the calyx: tube and throat short: upper lip upright, concave, entire; lower lip trifid: the middle segment more produced, emarginate: the stamina have four filaments, under the upper lip, of which two are shorter: anthers simple: the pistillum is a four-parted germ: style the size and situation of the stamens: stigma bifid: there is no pericarpium: fruit turbinate, truncate, in the bottom of the open calyx: the seeds four, convex on one side, angular on the other, at top wide and truncate.

The species cultivated are: 1. *M. laevis*,

Smooth Molucca Baum; 2. *M. spinosa*, Prickly Molucca Baum.

The first has an annual root: the stem three feet high, spreading out into many branches, which are smooth, and come out by pairs: the leaves are roundish, deeply notched on their edges, opposite, on long petioles, smooth, light green on both sides: at the base of the petioles the flowers come out in whorls: immediately under the calyx also come out two bunches of pretty long spines, one on each side, each bunch consisting of five or six spines arising from the same point: the corolla is small, and being placed at the bottom of the large calyx is not visible at a distance; it is white with a cast of purple. It is a native of Syria, flowering in July and August.

In the second the root is also annual: the stems smooth, purplish, four feet high, branching out in the same manner with the first: the leaves are smaller, on shorter foot-stalks, deeper and more acutely indented on their edges: the calyx not so large, and cut into eight segments, each terminated by an acute spine: the flowers like those of the first sort. It is a native of the Levant, flowering in July and August.

Culture.—These plants may be increased by sowing the seeds in the early autumn on a mild hot-bed, or in pots plunged into it, and when the plants have attained a little growth be planted in small pots, and placed under a hot-bed frame in winter, where they may have free air in mild weather by taking off the glasses, being carefully covered in frosty weather, keeping them pretty dry, otherwise they are apt to rot. In the spring the plants may be turned out of the pots, with their earth about their roots, and planted in a warm border, defended from strong winds, giving them a little water to settle the earth to their roots; after which they require no other care but to be kept clean from weeds, and be supported with stakes.

They afford ornament and variety in the borders among other tender annuals.

MOLY. See **ALLIUM**.

MOMORDICA, a genus furnishing plants of the annual trailing and perennial kinds.

It belongs to the class and order *Momectia Syngenesia*, and ranks in the natural order of *Cucurbitaceae*.

The characters are: that in the male flowers the calyx is a one-leaved perianthium, concave, five-cleft: segments lanceolate, spreading: the corolla five-parted, fastened to the calyx, more spreading, large, veined, wrinkled: the stamina have three awl-shaped filaments, short: anthers on two filaments bifid, eared at the sides; on the third simple, one-eared only, consisting of a compressed

body and a fariniferous line once reflex: female flowers on the same plant: the calyx is a perianthium as in the male, superior, deciduous: the corolla as in the male: the stamina have three filaments, very short, without anthers: the pistillum is an inferior germ, large: style single, round, trifid, columnar: stignas three, gibbous, oblong, pointing outwards: the pericarpium is a dry, oblong pome, opening elastically, three-celled: cells membranaceous, soft, distant: the seeds several, and compressed.

The species cultivated are: 1. *M. balsamina*, Common Momordica, or Male Balsam Apple; 2. *M. charantia*, Hairy Momordica; 3. *M. Luffa*, Egyptian Momordica; 4. *M. elaterium*, Elastic Momordica.

The first has a trailing stem, like those of the Cucumber and Melon, extending three or four feet in length, and sending out many side branches which have tendrils: the leaves are shaped like those of the Vine, smooth, deeply cut into several segments, and spreading open like the hand. According to Martyn, the fruit is fleshy, ovate, drawn to a point at each end, obscurely angular, remotely tubercled in longitudinal rows, smooth in the other parts, red when ripe, one-celled, inflated, bursting irregularly, and dispersing the seeds, which are ovate and pale brown, with a spring. It is a native of India, flowering in June and July.

The second species has a round, slender, branched stem, climbing by lateral tendrils: the leaves are sinuate-palmate, wrinkled, smooth, toothed, spread out into a ring, having the nerves pubescent; they are alternate and petioled: the flowers are sometimes hermaphrodite, on long, axillary, one-flowered peduncles, of a yellow or orange colour: the fruit oblong, bluntly angular, tubercled, drawn to a point at each end, white, yellow, or green on the outside; within very red and fleshy, one-celled; it bursts elastically: the seeds ovate, flat, bitten at the edge. It is a native of the East Indies, flowering in June and July. It varies, according to some, with short pointed fruit.

The third has an angular, very much branched stem, climbing by bifid spiral tendrils: the leaves having five or seven sharp angles, the middle one double the length of the others, unequally serrate, veined, wrinkled, on long alternate petioles: the male flowers are several together, terminating: the females lateral, and solitary: the pome a foot long, two inches thick, roundish, usually drawn to a point at each end, hairy, three-celled, with a white, flaccid, esculent pulp, of an insipid flavour: the seeds are oblong, compressed, and smooth. It is a native of the East Indies, flowering in July and August.

The fourth species has a large fleshy perennial root, somewhat like that of Bryony: the stems thick, rough, trailing, dividing into many branches, and extending every way two or three feet: the leaves are thick, rough, almost heart-shaped, gray, on long foot-stalks: the flowers axillary, much less than those of the common Cucumber, of a pale yellow colour, with a greenish bottom: the male flowers stand on short thick peduncles; but the female flowers sit on the top of the young fruit, which grows to an inch and half in length, swelling like a Cucumber, of a gray colour like the leaves, and covered with short prickles: the fruit does not change its colour, but when ripe quits the peduncle, and casts out the seeds and juice with great violence. It is a native of the South of Europe.

When the fruit is designed for medicinal use, it should be gathered before it is ripe, otherwise the greatest part of the juice, which is the only valuable part, is lost, as the expressed juice is not to be compared with that which runs out of itself; and the elaterium made from the clear juice is whiter, and keeps much longer than that which is extracted by means of pressure. All the parts of the plant are bitter, and strongly purgative.

Culture.—All these plants may be increased by sowing the seeds in the first three sorts upon a moderate hot-bed in the early spring months, as about March; and when the plants have had a little growth, let them be pricked out into another hot-bed, fresh air being given in fine weather, and water occasionally; or they may be let remain in the first hot-bed till they have acquired sufficient growth, and have four or five leaves, when they should be removed into the hot-bed where they are to remain, one or two plants being put into each light, due shade and water being given till fresh rooted. They afterwards demand the same management as the Cucumber kind, the branches being suffered to extend themselves in the same manner. When thus managed and properly treated in respect to air and water, they produce fruit and ripe seeds in the latter end of summer, when it must be immediately gathered to prevent its being dispersed.

The plants may likewise be set in pots, and placed in the hot-house, their vines or stems being supported by sticks, in which mode they have a much better appearance and effect.

The fourth sort may be sown or suffered to scatter, where the plants are to remain, or on beds of fine mould in the autumn; the plants being afterwards thinned out or removed into rows in an open situation, three or four feet apart, and as many distant in them, requiring only the

further culture of being kept clean from weeds. When the soil is dry, they often continue three or four years.

All the sorts afford ornament, the first three sorts in the stove, and the last in the open borders. The fruit of the last also affords a medicinal substance by inspissation.

MONARDA, a genus containing plants of the fibrous-rooted herbaceous flowery biennial and perennial kinds.

It belongs to the class and order *Diandria Monogynia*, and ranks in the natural order of *Verticillatae*.

The characters are: that the calyx is a one-leaved tubular perianthium, cylindric, striated, with a five-toothed equal mouth, permanent: the corolla unequal: tube cylindric, longer than the calyx: border ringent: upper lip straight, narrow, linear, entire; lower lip reflex, broader, trifid; middle segment longer, narrower, emarginate; lateral blunt: the stamina have two bristle-shaped filaments, the length of the upper lip, in which they are involved: anthers compressed, truncate at top, convex below, erect: the pistillum is a four-cleft germ: style filiform, involved with the stamens: stigma bifid, acute: there is no pericarpium: calyx containing the seeds at the bottom: the seeds four, roundish.

The species cultivated are: 1. *M. fistulosa*, Purple Monarda; 2. *M. oblongata*, Long-leaved Monarda; 3. *M. didyma*, Scarlet Monarda, or Oswego Tea; 4. *M. rugosa*, White Monarda; 5. *M. punctata*, Spotted Monarda.

The first has a perennial root, composed of many strong fibres, and spreading far on every side: the stems, near three feet high, are hairy and obtuse-angled; they send out two or four small side branches towards the top: the leaves oblong, broad at the base, but terminating in acute points, hairy, a little indented on their edges, on short hairy foot-stalks: the stem and branches terminating by heads of purple flowers, which have a long involucre, composed of five acute-pointed leaves. It is a native of Canada, flowering from June to August.

The second species differs from the first, in having the leaves ovate at the base, and a little attenuated, and more villose underneath. It is a native of North America, flowering from July to September.

The third has a perennial root: the stems about two feet high, smooth, acute-angled: the leaves indented on the edges, on very short foot-stalks; when bruised they emit a very grateful refreshing odour: towards the top of the plant come out two or four small side branches, with smaller leaves of the same shape: the flowers are

produced in large heads or whorls at the top of the stalk, and there is often a smaller whorl at a joint below the head; and out of the head arises a naked peduncle, sustaining a small head or whorl: the flowers are of a bright red colour. They come out in July; and in a moist season, or when the plants grow in a moist soil, they continue till the middle or end of September. It is a native of North America.

The fourth species resembles the following, but the leaves are longer, smooth, wrinkled a little like those of Sage, and the flowers white. It is a native of North America, flowering from July to September.

The fifth has stems about two feet high, branching out from the bottom to the top: the leaves lanceolate, coming out in clusters at each joint, where there are two larger leaves, and several smaller ones on each side; the larger leaves are two inches and a half long, three quarters of an inch broad, and slightly indented on their edges: towards the upper part of the stem the flowers come out in large whorls, with an involucre to each whorl composed of ten or twelve small lanceolate leaves, of a purplish red colour on their upper side (four larger, and four smaller, besides the leaves of the whorls): the flowers are pretty large, of a dirty yellow colour spotted with purple. It is a biennial plant; and a native of Maryland and Virginia, flowering here from June to October.

Culture.—All these plants may be increased by parting the roots, and some of them by slips and cuttings as well as seeds.

As the first sort does not increase fast by the roots, the seeds may be sown in the autumn on a bed of good earth, and in the following summer the plants be removed into nursery rows half a foot apart, in a rather shady situation, and in the beginning of the following autumn set out where they are to remain and flower. They succeed best in a soft loamy soil not too much exposed.

The roots should be divided either in the autumn or very early spring, but the former is the better, being afterwards either planted out in rows to remain till they are strong, or, when strong, at once where they are to remain.

Strong slips or cuttings of the branches may be taken off in the beginning of summer, and planted out in a shady border, due shade and water being given till well rooted, when in the autumn they may be removed to where they are to remain.

The third sort succeeds best in a light soil, in an eastern situation.

They all afford ornament in the borders and clumps of pleasure-grounds.

MONKEY-FLOWER. See *MIMULUS*.

MONKEY'S-BREAD. See *ADANSONIA*.

MONK'S-HOOD. See *ACONITUM*.

MONK'S-RHUBARB. See *RUMEX*.

MONSONIA, a genus containing plants of the herbaceous under-shrubby biennial and perennial kinds, for the green-house.

It belongs to the class and order *Monadelphia Dodecandria*, and ranks in the natural order of *Grinales*.

The characters are: that the calyx is a five-leaved perianthium: leaflets lanceolate, awned, equal, permanent: the corolla has five petals, obovate, præmorse-toothed, longer than the calyx, inserted into the base of the pitcher of stamens: the stamina have fifteen filaments, united in five bodies, three in each, all connected at the base, and forming a very short pitcher: anthers oblong: the pistillum is a five-cornered short germ: style awl-shaped: stigmas five, oblong: the pericarpium is a five-cornered capsule, five-celled: each cell fixed to a very long, twisted, terminating tail: the seeds solitary.

The species are: 1. *M. speciosa*, Fine-leaved Monsonia; 2. *M. lobata*, Broad-leaved Monsonia; 3. *M. ovata*, Undulated Monsonia.

The first has the radical leaves petioled, several, bipinnate-quinate: leaflets linear, pinnate, pinnasublanccolate: the scapes two or three, one-flowered, a span high, twice as long as the leaves, having in the middle a small six-leaved involucre, with lanceolate leaflets: the flower handsome: in habit and fructification it bears great affinity to Geranium, but is distinguished from it by having the appearance of Anemone, and by the stamens and style being different.

The second species is very like the preceding, differing in no respect from it, not even in the very singular crown of the germ; but the leaves are simple, bluntly seven-lobed, crenate, blunt, subpubescent (as the whole herb is), entirely resembling those of some sorts of Geranium: the fruit has a beak to it, with a very long point.

The third has the stem herbaceous, columnar, and filiform: the leaves opposite, about equal in length to the foot-stalks, ovate, crenated, about half an inch long, with some hairs: the stipules are two on each side, subulate: the flowers are axillary, on very long foot-stalks, of a whitish yellow colour; about the middle of the length of the foot-stalk are two stipules: the foot-stalk of the flowers is upright: when bearing the fruit it is declinate-erect from the stipules, one-flowered.

All these plants are natives of the Cape; the two first being perennial, flowering in April

and May, and the third biennial, flowering in August.

Culture.—The first sort rarely, if ever, ripening seeds in this climate, must be increased by cuttings of the root, which should be planted in pots of good mould, and plunged in a tan-hot-bed, watering them occasionally, when in a little time buds appear on the tops of the cuttings which are left out of the ground. They should be treated as hardy green-house plants, or be afterwards removed into separate pots, and sheltered under a good garden frame in the winter season.

And the second sort should be raised in the same manner.

But the third should be raised from seeds, which must be sown in the early spring in pots of light earth, and plunged in a mild hot-bed. When the plants are come up, they should be removed into other pots separately, and be managed as the other kinds.

They afford variety among other potted plants.

MOON TREFOIL. See *MEDICAGO*.

MORÆA, a genus furnishing plants of the bulbous-tuberous-rooted herbaceous flowering perennial kinds.

It belongs to the class and order *Triandria Monogynia*, and ranks in the natural order of *Ensatiæ*.

The characters are: that the calyx has two-valved spathes: the corolla six-petalled: three inner parts spreading; the rest as in Iris: the stamina consist of three short filaments: anthers oblong: the pistillum is an inferior germ: style simple: stigmas three, bilid: the pericarpium is a three-cornered capsule, three-grooved, three-celled: the seeds very many, round.

The species cultivated are: 1. *M. Iriopetala*, Iris-petalled Moræa; 2. *M. Iridioides*, Iris-like Sword-shaped Moræa.

The first sort has two varieties, the first of which has the bulb with the scales connected at the sides a little compressed, but distinct at the base: with ten compressed teeth, and as many alternately shorter: the skin smooth, and dark-coloured: the culm branched: branches three or four: the leaves three or four, awl-shaped, pale-green, from five to seven or eight inches in length, and about half an inch broad, terminating with three angles; the glumes two-valved, subglobular, two-flowered: the flowers are white: the seeds of a reddish rust colour. It is a native of the Cape, flowering in June.

The second has the scales connected at the base, bilid, depressed, but not compressed: the glume two-valved, two-flowered: the flowers two, seldom more than two on a scape: the roots are fibrous, like those of the Hag-leaved

Iris, whence arise many small sword-shaped leaves, five or six inches long, and half an inch broad in the middle, diminishing towards both ends, of a deep green colour, lying over each other at the base: the scape about eight inches high, having one small leaf at each joint, and terminated by one flower, covered with a two-valved spathe, of a dirty white, with a blush of purple. It is a native of the Cape, flowering in June, and ripening seeds about the end of July.

The second species has a fibrous root; the scape a span or foot high, roundish or scarcely compressed, jointed, smooth, simple or little branched, upright, the length of the leaves: the leaves ensiform, narrowed at the inner base, nerved, smooth, acuminate, upright: the flowers from the uppermost axils of the leaves, sometimes three, but often only one: the spathe two-valved: the germ pedicelled, subtrigonal, striated: the corolla is six-petalled: the three outer petals obovate, oblong, bearded, spreading, with a yellow spot in the middle: the three inner white without spots, spreading like the outer ones: the seeds numerous, variously angular, depressed, with two flat sides. It is a native of the Cape.

Culture.—These plants are all increased either by seeds, offsets, or parting the roots, which should be performed in August, in all the methods; the seeds being sown in small pots, and plunged into a bed of old tanner's bark, under a common frame. The seed is chiefly sown for the sake of raising new varieties.

The plants also require the shelter of a frame in winter, being apt to draw up weak when placed in the dry stove. Where they can enjoy the free air in winter, when the weather is mild, and be secured from frost and hard rain, they flower and ripen their seeds better than with more tender management. In summer they should be fully exposed to the open air till the approach of autumn, when they should be removed into the shelter of the frame.

They afford variety among other potted plants in the green-house, &c.

MORINA, a genus furnishing plants of the hardy herbaceous flowery perennial kind.

It belongs to the class and order *Diandria Monogynia*, and ranks in the natural order of *Aggregatæ*.

The characters are: that the calyx is double: the perianthium of the fruit inferior, one-leaved, cylindric, tubular, permanent: mouth toothed: toothlets two, opposite, longer; all subulate, acute: perianthium of the flower superior, one-leaved, tubular, bifid; segments emarginate, blunt, permanent, upright, the size of the outer: the corolla one-petalled, two-lipped: tube very

VOL. II.

long, widening above, a little curved in, filiform at bottom: border flat, blunt, upper lip semi-bifid, smaller; lower trifid; segments all blunt, uniform, the middle one more lengthened: the stamina have two bristle-shaped filaments, approximating to the style, parallel, shorter than the border: anthers erect, cordate, distant: the pistillum is a globular germ, under the receptacle of the flower: style longer than the stamens, filiform: stigma headed-peltate, bent in: there is no pericarpium: the seed single, roundish, crowned with the calyx of the flower.

The species is *M. Persica*, The Persian or Oriental Morina.

It has a taper and thick root, running deep into the ground, sending out several thick strong fibres as large as a finger: the stem nearly three feet high, smooth, purplish towards the bottom, but hairy and green at the top: at each joint are three or four prickly leaves, four or five inches long, an inch and half broad, of a lucid green on the upper side, but of a pale green and a little hairy underneath, armed on their edges with spines; the flowers axillary on each side, some white and others purplish red on the same plant; appearing in July, but do not produce seed in this climate. According to some it has the odour of Honeysuckle. It is a native of Persia near Ispahan.

Culture.—This is increased by seed or off-sets from the roots.

The seeds should be sown in the autumn in the places where the plants are to grow, as, from their having a strong tap-root, they do not bear shifting well. The ground in the bed or border near them should not be afterwards much disturbed, the plants being only kept clean. They mostly flower in two or three years after being raised.

The off-sets should be slipped from the roots while young, and be planted out where they are to stand, in the latter end of the summer, being afterwards treated as those raised from seed.

They decay to the ground in the autumn, new leaves being sent up in the spring; but the roots continue several years when not stirred, or injured by severe frosts.

They are highly ornamental in the principal beds and borders of pleasure-grounds.

MOROCCO, RED. See *ADONIS*.

MORUS, a genus containing plants of the deciduous tree kind.

It belongs to the class and order *Monocelia Tetrandria*, and ranks in the natural order of *Scabridæ*.

The characters are: that the male flowers are in an ament: the calyx is a four-parted perianthium: leaflets ovate, concave: there is no corolla: the stamina have four awl-shaped fila-

S.

ments, erect, longer than the calyx, one within each calycine leaf: anthers simple: female flowers heaped either on the same, or a different individual from the males: the calyx a four-leaved perianthium: leaflets roundish, blunt, permanent, the two opposite outer ones incumbent: there is no corolla: the pistillum is a cordate germ: styles two, awl-shaped, long, reflex, rugged: stigmas simple: there is no pericarpium: calyx very large, fleshy, become succulent, like a berry: the seed single, ovate, acute.

The species cultivated are: 1. *M. nigra*, Common Mulberry Tree: 2. *M. alba*, White Mulberry Tree: 3. *M. papyrifera*, Paper Mulberry Tree: 4. *M. rubra*, Red Mulberry Tree: 5. *M. indica*, Indian Mulberry: 6. *M. tinctoria*, Dyer's Mulberry or Fustick-wood.

The first differs from the second sort, according to Linnæus, in having the leaves subquincquelobate, bluntish, and rugged, undivided and shining; the fructification of the second dioecious, of this monœcious. These distinctions are not however exact, as this is a larger, stronger tree; and the fruit is dark blackish red and more acid. According to Miller, it has generally male flowers or catkins on the same tree with the fruit, but it often happens that some of the trees which are raised from seeds have mostly male flowers and produce no fruit; and he has observed some trees which produced only catkins for many years after they were planted, and afterwards have become fruitful. "This," Martyn says, "agrees with a general remark that he has made on monœcious trees, that whilst they are young they bear male flowers chiefly and very little fruit." Trees of this sort of a certain age are not only more fruitful than young ones, but their fruit is much larger and better flavoured. It grows naturally in Persia; whence introduced into Europe.

This is the sort usually cultivated as a fruit-tree in the garden.

There is a variety with palmate or elegantly cut leaves and a smaller fruit.

The second species is a middle-sized tree, with a whitish bark, of which a coarse sort of paper may be made, and spreading branches: the leaves are broad-lanceolate, obliquely cordate, subserrate, undivided, or three-lobed, some cut, smooth, petioled, scattered: the berries lateral, juicy, insipid, pale, oblong. It is a native of China, &c. flowering in June.

Miller observes that there are two or three varieties of this tree, which differ in the shape of their leaves, and in the size and colour of the fruit; but as it is of no other use but for the leaves, the strongest-shooting and the largest-leaved should be preferred.

This sort is commonly cultivated for its leaves to feed silk-worms in France, Italy, &c.; and in Spain, according to Mr. Townsend, they prefer the White Mulberry in Valencia, and the Black in Granada. But the Persians generally make use of the latter; and Mr. Miller was assured by a gentleman who had made trial of both sorts of leaves, that the worms fed with the latter produced much the best silk; but that the leaves of the black should never be given to the worms after they have eaten for some time of the white, lest they should burst. And Sir George Staunton states, that the tender leaves growing on the young shoots of the black sort are supposed in China to be the most succulent or juicy.

The third is a tree which makes very strong vigorous shoots, but seems not to be of tall growth, as it sends out many lateral branches from the root upwards. The leaves are large, some of them entire, others deeply cut into three or five lobes, especially whilst the trees are young; they are dark green and rough to the touch on the upper surface, but pale green and somewhat hairy on the under side, falling off on the first approach of frost in autumn. The fruit is little larger than peas, surrounded with long purple hairs, when ripe changing to a black-purple colour, and full of sweet juice. It is a native of Japan and the South Sea islands.

The fourth species, which is the Virginian Red or Large-leaved Mulberry Tree with black shoots, grows to the height of thirty or forty feet in its native situation, sending forth many large branches. The leaves are not only larger but rougher than those of the common Mulberry, though in other respects they somewhat resemble them. It produces plenty of catkins, in shape like those of the Birch, and it has a dark reddish fruit. It is a native of Virginia and Carolina.

The fifth is a large tree, with a soft, thick, yellowish bark, and a milky juice like the Fig, which is astringent. The branches come out on every side. The leaves are on short footstalks, rough, dark green above, pale underneath, alternate. The flowers in round heads, at the footstalks of the leaves, on each side the branches, of an herbaceous white colour: the fruit roundish, first green, then white, and finally dark red. According to Miller it is a monœcious tree, but Linnæus suspects it to be dioecious. It is a native of the East Indies.

The sixth species is a tall branching tree with a fine head, the whole abounding in a slightly glutinous milk of a sulphureous colour: the timber is yellow, and is used in dyeing: the spines awl-shaped, solitary, few; entire branches are frequently without any: the leaves acuminate, serrate, smooth on both sides, veined, distichous,

on short petioles of various sizes : aments solitary, pendulous, axillary between the petiole and the spine, two or three inches in length, cylindrical and very close : the female flowers on a different tree, collected into a globe : their receptacles axillary, glaucous-green, solitary, with short petioles : among the female flowers are some chaffy bodies, which perhaps were flowers suffocated by their neighbours and dried up : the fruit yellowish green, sweet, but eaten chiefly by birds. It is a native of Brazil.

Culture.—All the sorts are capable of being increased by seeds, layers, cuttings, grafting, and inoculating or budding.

The seed method is chiefly practised for those which are not intended as fruit-trees, as they are very liable to vary in that way. It should be sown in the early spring, as about March, on a bed of fine earth, in a warm aspect, or upon a moderate hot-bed protected with glasses, in drills to the depth of a quarter of an inch. Water should be given slightly in dry weather ; and in the heat of the day shade ; covering it in cold nights. When the plants appear, they should be well guarded from frost in the early spring, and be kept clean during the summer, and properly shaded and watered, protecting them the first autumn and winter, removing them in the following March into nursery rows two feet apart, and one distant, to continue a few years, when they may be set out where they are to grow. They should not be removed, either from the seed-bed or nursery rows, till perfectly strong.

When intended for feeding silk-worms, they should be kept in a low shrubby state.

They appear, from Sir George Staunton, to succeed best in China, on beds about a foot high in moist loamy soils.

When raised for fruit, great care should be taken that the layers or cuttings be not only taken from old fruit-bearing trees, but that the branches made use of be also fruit-bearing.

The layers may be made from stools formed for the purpose, or by raising large boxes, baskets, or pots of earth, so as to lay the branches in them in the autumn, by the slit method, heading them down to two eyes each. When they have taken root in the autumn following, they may be removed into the nursery and managed as the seedlings.

The cuttings should be made from the former year's shoots of such trees and branches as bear well, and have fine fruit, not being shortened, but planted their whole length, leaving two or three buds above the ground. They should be planted in March on light rich earth, pressing the mould well about them, in order that it may be kept from getting too dry.

When well rooted in the following spring, they may be removed into the nursery, being regularly trained to stems by means of stakes fixed to each of them, to which the principal shoots should be trained, removing most of the rest, except such as are necessary to detain the sap for the support of the stem.

They may be trained to Standards, Half Standards, and Dwarf Standards. See PRUNING and TRAINING.

After standing three or four years in the nursery, they will be ready to plant out for good.

They should have but little sun at the first planting of the cuttings, but afterwards as much as possible, provided the earth about them be prevented from becoming dry, by moss or other means. The cuttings also succeed well when planted in a hot-bed ; and in all cases when covered by hand glasses.

Some also plant them in October.

The grafting and budding, or inoculating, are certain methods of continuing the proper kinds, and should be practised in the usual manner upon the seedling stocks of any of the species. See GRAFTING and BUDDING.

Mr. Forsyth remarks, that "as the fruit is produced on the young wood, only such branches as cross others, and such as are decayed, or broken by accident, should be cut out, applying at the same time the composition. When, however, the heads become too full of wood, it will, he thinks, be necessary to thin them, as the fruit is larger and better flavoured where the heads are kept thin of wood."

He advises planting these trees, when for fruit, in grass orchards and pleasure-grounds, as "the finest of the fruit, when ripe, frequently drops, which, if it fall on dug or ploughed ground, will be soiled and rendered unfit for use, as the earth will adhere so to the fruit as to render the cleaning of it impracticable ; but if planted on lawns, or in grass orchards, the fruit can be picked up without receiving any injury. Another reason for planting these trees on lawns or in orchards is," he says, "that when full grown, they are too large for a kitchen-garden. The soil in which they thrive best is a rich, light, and deep earth."

"He has tried the efficacy of his composition on several of these trees in a very decayed hollow state of the trunk, cutting out all the dead wood and cankered parts of some, and heading down others that were stunted and sickly. After these operations they put forth vigorous branches, and bore excellent crops of fruit, more than double the size of that which they produced in their former state."

And he advises "those who have any old

decayed Mulberry-trees, to treat them in the same manner; but those which are very much decayed should be headed down; this will throw them into a healthy bearing state, and in two or three years they will, he asserts, produce plenty of fine fruit."

And as old trees of this sort bear better and have finer fruit than young ones, it is of importance, he thinks, to restore them.

The fifth and sixth sorts are tender, requiring the protection of the bark stove.

The first sort is raised for the fruit; but the others chiefly for the purpose of variety and ornament. The third is used for having the bark made into paper in some countries.

MOSSING OF FRUIT-TREES. This is a disease arising from the Moss Plant establishing itself upon such fruit-trees as are in an unhealthy state of growth or which are planted so close together as to prevent a due circulation of air and dryness. The trees, by this means, are not only injured, from the plant fixing itself upon them, and restricting their growth, but probably by the quantity of moisture that it attracts, and the dampness that is produced in that way.

For the prevention and removal of this state of fruit-trees, Mr. Forsyth advises the washing them with a mixture of fresh cow-dung, urine and soap-suds, as by this means the moss is not only prevented from growing on the trunks and branches, but the ova of insects are destroyed, the trees nourished, and the bark kept in a fine healthy state. It may also be removed by scraping the trees.

Apple-, Pear-, and Plum-trees are very liable to be affected in this way.

MOTION OF PLANTS, the course or direction of growth in different parts of them.

In the roots and stems the direction is totally opposite, the former either running directly downward into the ground, or horizontally under the surface; while the latter direct their motion towards the air and light of the sun, mostly in an upright manner, but sometimes horizontally along the surface of the ground. The causes which operate in promoting these are the quest of nourishment in the root, and the influence of the air and light of the sun on the stem; for when any number of plants growing in pots is placed in a room, which only admits a small portion of light at one place, the stems all incline towards that side; in close dark thickets, the young trees always lean to the part where the most light penetrates; and the new shoots of espalier or wall-trees detach themselves from those supports, in quest of free air and light.

It seems that the force of motion is greater in

the roots than in the stems; the roots, without ever once going out of their way, pierce the hardest soils, penetrate into walls, which they overturn, and even into rocks, which they split; whereas the stems and branches surmount obstacles by leaving their natural direction, and over-topping them.

Though the natural tendency of most stems or trunks is to ascend, some by their weakness, or natural growth, descend: and occasionally by means of roots breaking out all along the stems and branches, as in the Strawberry, Penny-royal, and many other creeping plants, the stems are, by the roots striking into the earth, tethered as it were to the ground, and only their extremities have the power of directing their course upwards.

The leaves and flowers of plants also direct their course towards the air, and light of the sun; the leaves always turning their upper surface outward to the air and light; which is very obvious in Wall-trees, and when a branch is overturned, so that the leaves are inverted, they naturally direct their surfaces again gradually upwards to the light and air, though this often takes them several days' growth. Some flowers are also supposed to have a particular daily motion, so as to present their surfaces directly to the sun, and follow the diurnal course of it, as the Sun-flower, and most of the compound flowers; in all of which the disk or surface is believed to look towards the east in the morning, the south at noon, and the west in the evening.

And during the heat of the sun, the pinnated or winged leaves, particularly of the papilionaceous tribe of plants, rise vertically upward; the opposite lobes or folioles, which compose these leaves, rise so as to be generally applied close together by their upper surfaces; but in that state of the atmosphere which generally precedes a storm, or during a close, moist, cloudy air, the lobes of the same sort of leaves extend themselves commonly along the foot-stalk; and after sun-set incline still lower, and hang directly down under the foot-stalk, being applied close together like the leaves of a book, by their lower surfaces; a state which by Linnæus is called the sleep of plants.

The simple leaves of many plants, when their surface is exposed to an ardent sun, also become concave above, but gradually recover as the heat declines. But, of all the motions of the leaves of plants, none is so sudden and rapid as those of the Sensitive and Humble kinds.

There is another kind of motion in plants; that is, elasticity; which is resident particularly in some sorts of seed-vessels, such as the Yellow Balsamine, and Spurting Cucumber, &c. in which their fruits, when arrived at maturity,

burst open like a spring, and dart out their seeds with an elastic force to a considerable distance in many cases.

MOULD, such earthy substances as constitute soils, when reduced into a fine pulverized state in their particles. It is of different qualities according to the nature of the earth or soil in which it is found. But the best is probably that which contains a large proportion of carbonaceous or vegetable matter. It is of very different colours in different cases, as hazel, dark-gray, russet, ash, yellowish red, and various others. But the first three colours are generally considered as denoting the best qualities, and the last the most unfriendly for the growth of vegetables.

For the purpose of the gardener, those moulds which are capable of working well at all seasons, are rather light and dry, perfectly mellow and fine in their particles, being well enriched with vegetable and animal matters, are the most proper and capable of affording the largest crops of good vegetables. See **EARTH** and **SOIL**.

MULCH, a term made use of in gardening to signify such strawy dung as is somewhat moist and not rotted. It is found useful for protecting the roots of new-planted choice trees or shrubs from severe frost in winter, and from being dried by the fierce sun or drying winds in spring and summer, before they are well rooted; in which cases it is spread evenly on the surface of the ground round the stems of the trees, as far as the roots extend, about three or four inches thick, but which should be augmented in winter, when the severity of the frost renders it necessary. It may also be employed for many other purposes.

MOUNTAIN ASH. See **SORBUS**.

MOUSE-EAR. See **HIERACIUM**.

MUGWORT. See **ARTEMISIA**.

MULBERRY-TREE. See **MORUS**.

MUSA, a genus containing plants of the perennial kind for the hot-house.

It belongs to the class and order *Polygamia Monoecia*, and ranks in the natural order of *Scitamineae*.

The characters are: that the hermaphrodite flowers are more towards the base of the simple spadix, separate in alternate spathes: the calyx is a partial, ovate-oblong spathe, plano-concave, large, many-flowered: the corolla unequal, ringed: the petal constituting the upper lip, but the nectary the under lip: petal erect, ligulate, truncate, five-toothed, converging in front at the base: nectary one-leafed, cordate, boat-shaped, compressed, acuminate, spreading outwards, shorter than the petal, inserted within the sinus of the petal: the stamina have six

awl-shaped filaments, five of which within the petal are erect, the sixth within the nectary is reclining: anthers linear, from the middle to the top fastened to the filament; but most frequently there is only one anther on the sixth filament, and very small ones or none on the rest: the pistillum is a very large germ, obtusely three-sided, very long, inferior: style cylindric, erect, the length of the petal: stigma headed, roundish, obscurely six-cleft: the pericarpium is a fleshy berry, covered with a husk, obscurely three-sided, or six-sided, gibbous on one side, one-celled, hollow in the middle: the seeds very many, nestling, subglobular, wrinkled-tubercled, excavated at the base, or only rudiments: males on the same spadix, above the hermaphrodite flowers, separated by spathes: the calyx, corolla, and nectary as in the hermaphrodite: the stamina have filaments as in the hermaphrodites, equal, erect: anthers as in hermaphrodites, on the filament placed within the nectary, most frequently very small or none: the pistillum is a germ as in the hermaphrodites, but less: style and stigma as in them, but less and more obscure: the pericarpium is abortive.

The species cultivated are: 1. *M. paradisiaca*, Plantain Tree: 2. *M. sapientum*, Banana Tree.

The first rises with a soft herbaceous stalk, fifteen or twenty feet high, and upwards, in its native situation: the lower part of the stalk is often as large as a man's thigh, diminishing gradually to the top, where the leaves come out on every side, which are often more than six feet long and near two feet broad, with a strong fleshy midrib, and a great number of transverse veins running from the midrib to the borders: the leaves are thin and tender, so that where they are exposed to the open air they are generally torn by the wind; for, as they are large, the wind has great power over them: these leaves come out from the side of the principal stalk, inclosing it with their base; they are rolled up at their first appearance, but when they are advanced above the stalk they expand quite flat, and turn backward: as these leaves come up rolled in the manner before mentioned, their advance upward is so quick, that their growth may be almost discerned by the naked eye; and if a line is drawn across, level with the top of the leaf, in an hour's time the leaf will be near an inch above it: when the plant is grown to its full height, the spike of flowers will appear from the centre of the leaves, which is often near four feet in length, and nods on one side: the flowers come out in bunches, those on the lower part of the spike being the largest; the others diminish in their size upward; each of these bunches is covered with a spathe or sheath, of a fine purple colour

within, which drops off when the flowers open : the upper part of the spike is made up of male or barren flowers, which are not succeeded by fruit : the fruit is eight or nine inches long, and above an inch diameter, a little incurved, and has three angles ; it is at first green, but, when ripe, of a pale yellow colour, having a tough skin, within which is a soft pulp of a luscious sweet flavour : the spikes of fruit are so large as to weigh upwards of forty pounds in some cases. It is a native of the East Indies, flowering from October to November.

The second species, or Banana Tree, differs from the preceding in having its stalks marked with dark purple stripes and spots : the fruit is shorter and rounder, with a softer pulp of a more luscious taste : but Mr. Dampier says, it is less luscious, though of a more delicate taste. And according to Long, it has a softer, mellow taste, and is more proper for fritters than the Plantain. A very excellent drink is made from the juice of the ripe fruit fermented, resembling the best Southam cyder. It is found in the West Indies.

There are several varieties of each species.

It is observed by Brown, that "these two fruits are among the greatest blessings bestowed by Providence upon the inhabitants of hot climates." And that "three dozen Plantains are sufficient to serve one man for a week instead of bread, and will support him much better."

Culture.—These plants may be increased by planting the young suckers of the roots of such plants as have fruited, taken off carefully with root-fibres, in large pots filled with light rich earth, and plunged in the tan-bed of the stove, in the summer season.

They afterwards require to have water given pretty plentifully in the hot summer months, but more sparingly in the winter, and in less proportions at a time. They succeed best in about the same degrees of heat as the Pine Apple. They should have the pots increased in size as they advance in growth.

But the best way to have them fruit well in this climate is to shake them out of the pots, after they have become fully established, with the balls of earth about their roots, and plant them in the tan-bed in the stove, old tan being laid round them for their root-fibres to strike into.

When new tan is added, care should be taken not to disturb their roots, and always to leave plenty of old tan about them, to guard against too much heat. They should have water twice a week in winter, about two quarts each plant at a time, and in summer twice as much at a time and every other day. The signs of per-

fecting their fruit, are their pushing out their flower-stems in the spring. The stoves should be sufficiently high for this purpose, as twenty feet or more.

In their native country, these trees thrive best where the soil is rich, cool, and moist. Their fruiting in the South Sea islands is said to be promoted by the use of lime and wood-ashes.

They are mostly cultivated here by way of curiosity and for variety.

MUSHROOM. See AGARICUS.

MUSTARD. See SINAPIS.

MYRICA, a genus furnishing plants of the deciduous and evergreen shrubby kinds.

It belongs to the class and order *Dioecia Tetrandria*, and ranks in the natural order of *Amentaceæ*.

The characters are : that in the male the calyx is an ovate-oblong ament, imbricate on all sides, loose, composed of one-flowered, crescent-shaped, bluntly acuminate, concave scales : perianthium proper none : there is no corolla : the stamens have four filaments (seldom six) filiform, short, erect : anthers large, twin, with bifid lobes : female—the calyx as in the male : there is no corolla : the pistillum is a subovate germ : styles two, filiform, longer than the calyx : stigmas simple : the pericarpium is a one-celled berry : the seed single.

The species cultivated are : 1. *M. Gale*, Sweet Gale, Sweet Willow, or Candle-Berry Myrtle ; 2. *M. cerifera*, American Candle-Berry Myrtle ; 3. *M. quercifolia*, Oak-leaved Candle-Berry Myrtle ; 4. *M. cordifolia*, Heart-leaved Candle-Berry Myrtle.

The first rises with many shrubby stalks, from two to near four feet high, dividing into several slender branches, and is covered with a dusky or rust-coloured bark, sprinkled with white dots : the buds are composed of nine leafy shining scales, the first nearly opposite, very short, rectangularly pointed, the rest ovate, and blunt : the leaves are alternate, stiff, an inch and half long, and half an inch broad in the middle, light or yellowish green, smooth, a little serrate towards their points, and emitting a fragrant odour when bruised ; which is occasioned by the resinous points with which they are sprinkled : they are convoluted and petioled : the flowers appear before the leaves ; and the flower-buds are above the leaf-buds, at the ends of the branches, whence as soon as the fructification is completed the end of the branch dies, the leaf-buds which are on the sides shoot out, and the stems become compound : the aments or catkins are of a short ovate figure, of a yellowish brown colour, and frequently sprinkled with shining resinous golden

particles : the fruit is a coriaceous berry : the male and female aments are sometimes on distinct plants, and sometimes on the same individual. It is a native of the northern parts of Europe.

It is said, that "the northern nations formerly used this plant instead of Hops," and that "it is still in use for that purpose in some of the Western Isles, and a few places of the Highlands of Scotland."

It is here known by the names of *Sweet Gale*, *Goule*, *Gule*, *Sweet Willow*, *Wild Myrtle*, and *Dutch Myrtle*.

The second species is a shrub, or a tree acquiring a height of thirty feet in its native state : the bark is warted : the branches unequal and straight : the leaves evergreen, somewhat clustered, blunt at the end, membranaceous-rigid, wrinkled, smooth, covered underneath with very minute, shining, orange-coloured, glandular pores : the flowers are in aments, on different individuals : the male aments, according to Miller, are about an inch long, and stand erect : and Martyn says, the female aments are sessile, axillary, linear, shorter than the leaves : scales very minute, and between each of them an oblong minute germ, longer than the scales : two filiform styles, the length of the germ ; and reflex stigmas : the berry minute, roundish, yellow. It is a native of America.

The third has the stalks slender, shrubby, about four feet high, dividing into smaller branches : the leaves are about an inch and half long, and almost an inch broad, some of them having two, others three deep opposite indentures on their sides ; they sit close to the branches, and end in obtuse indented points : between the leaves come out some oval catkins, which drop off : it retains its leaves all the year, and is a native of the Cape, flowering in June and July.

The fourth species has a weak shrubby stalk, five or six feet high, sending out many long slender branches, closely garnished their whole length with small heart-shaped leaves, sitting close to the branches, slightly indented and waved on their edges : the flowers come out between the leaves in roundish bunches : they have an uncertain number of stamens, and are all included in one common scaly involucre or cover. The leaves continue all the year green. It is also a native of the Cape.

Culture.—The first two sorts may be raised from seed, and the two last by layers. The first kind requires a boggy moist situation, or to be cultivated on bog earth in such circumstances.

The seeds should be procured from their native situation, and sown in pots of rich earth, in the

spring, to the depth of half an inch, watering and shading them during the following summer, and on the approach of winter placed in a warm sheltered situation, or under a common frame. When the plants have attained some growth, they should be planted out in the spring in nursery rows, to remain till of proper size to be planted out in the pleasure-ground, where they succeed best in a soil that is not too dry.

The two last sorts are mostly raised by laying down the young shoots in the latter end of summer or in the autumn, twining them at a joint, and watering them well during the following summer, when the season is dry ; and when they have formed good roots, which is seldom the case till the second year, they should be taken off and planted in small pots filled with soft loamy earth, being placed under glasses in a common frame, and shaded from the mid-day sun till fully rooted ; when they may be removed into a warm sheltered place during the summer, and in the autumn removed into the green-house, being afterwards managed as other plants of that kind.

The first sorts are likewise sometimes raised by planting the suckers of the roots in nursery-rows as above in the autumn ; and all the sorts occasionally by cuttings, though they strike root with great difficulty. In this last way the young shoots are the most proper, which should be planted in pots, and plunged in a hot-bed, covering them close with glasses.

They are introduced, the two first in sheltered clumps and borders, and the latter sorts in collections of the green-house kind, where they afford a fine fragrance in their leaves.

MYRSINE, a genus comprising a plant of the evergreen exotic shrubby kind.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Bicornes*.

The characters are : that the calyx is a five-parted perianthium, small : leaflets subovate, permanent : the corolla one-petalled, half-five-cleft : segments half-ovate, converging, blunt : the stamina have five filaments, scarcely visible, inserted into the middle of the corolla : anthers awl-shaped, erect, shorter than the corolla : the pistillum is a subglobular germ, almost filling the corolla : style cylindric, longer than the corolla, permanent : stigma large, woolly, hanging on the outside of the flower : the pericarpium is a roundish berry, depressed, one-celled : the seed one, subglobular, fixed obliquely to the bottom of the berry.

The species cultivated is *M. Africana*, African Myrsine.

It has the flowers axillary, in threes, on short

peduncles: the corolla is pale, rugged with testaceous dots; ciliate, closed: the stamens opposite to, not alternate with, the segments of the corolla: the stigma is pencil-shaped: the berry of the same form and shape with that of *Uva Ursi*, and blue: the nucleus of the same shape, globular, depressed a little. It is a native of the Cape, flowering from March to May.

Culture.—This plant may be increased by sowing the seeds in spring on a hot-bed; and when the plants are fit to transplant, planting them out singly into small pots of good mould, due shade and water being given, and in the autumn they may be removed into the green-house for protection in winter.

They may also be raised by planting cuttings of the young shoots in pots in summer, due shade and water being given. They afterwards require the management of other green-house plants.

They afford variety among collections of this sort of plants.

MYRTLE. See MYRTUS.

MYRTLE, CANDLEBERRY. See MYRICA.

MYRTLE-LEAVED SUMACH. See CO-

RIARIA.

MYRTO-CISTUS. See HYPERICUM.

MYRTUS, a genus furnishing plants of the evergreen shrubby kind for the green-house and stove.

It belongs to the class and order *Icosandria Monogynia*, and ranks in the natural order of *Hesperideae*.

The characters are: that the calyx is a one-leaved perianthium, four- or five-cleft, bluntish, superior, raised internally into a subvillose ring, permanent: the corolla has four or five petals, ovate, entire, large, inserted into the calyx: the stamina have very many capillary filaments, the length of the corolla, inserted into the calycine ring: anthers roundish, small: the pistillum is an inferior germ, two-celled or three-celled; the seeds fixed to the partition: style simple, filiform: stigma blunt: the pericarpium is an oval berry, umbilicated with the calyx, one-, two-, or three-celled: the seeds few, kidney-form.

The species cultivated are: 1. *M. communis*, Common Myrtle; 2. *M. tomentosa*, Woolly-leaved Myrtle; 3. *M. biflora*, Two-flowered Myrtle; 4. *M. lucida*, Shining Myrtle; 5. *M. dioica*, Dioecious American Myrtle; 6. *M. Zeylanica*, Ceylon Myrtle; 7. *M. acris*, Cut-leaved Myrtle; 8. *M. coriacea*, Sumach-leaved Myrtle; 9. *M. Pimenta*, Pimento, Jamaica Pepper, or Allspice.

The first is well known as an elegant evergreen shrub, but just too tender to abide the winter without some protection in this climate, except in the most southern and western parts:

the trunk is irregular, branching, covered with a brown rough scaling bark: the leaves ovate or ovate-lanceolate, entire, smooth on both sides, dark-green, paler underneath, opposite and decussated: the flowers come out singly from the axils, and have a two-leaved involucre under them. It is a native of Asia and the southern parts of Europe, flowering in July and August.

There are several varieties, the principal of which are:

The Common Broad-leaved or Roman Myrtle, which grows to the height of eight or ten feet in this climate, but much higher in Italy, where it is the principal underwood of some of the forests: the leaves are broader than most of the other varieties, being an inch in breadth; they are an inch and half long, of a lucid green, ending in acute points, and are sessile or on very short foot-stalks: the flowers are larger than those of the other varieties, on pretty long slender peduncles, from two to four at the same axil: the berries ovate, and of a dark purple colour. It is termed by some the *Flowering Myrtle*, because it flowers more freely here than the others, and *Roman Myrtle*, because it abounds about Rome.

The Box-leaved Myrtle, which has the leaves oval, small, sessile, of a lucid green, and ending in obtuse points; the branches weak, and frequently hanging down when permitted to grow without shortening; the bark is grayish: the flowers are small, and come late in the summer: the berries small and round.

The Common Italian Myrtle, which has ovate-lanceolate leaves ending in acute points; the branches grow more erect than in either of the preceding, as also the leaves, whence it is called by the gardeners *Upright Myrtle*. The flowers are not large, and the petals are marked with purple at their points, whilst they remain closed: the berries are small, oval, and of a purple colour.

There is a subvariety of this with white berries: and the *Nutmeg Myrtle* seems, according to Miller, to be only a subvariety of it.

The Orange-leaved, or what is sometimes termed Bay-leaved Myrtle, which has a stronger stalk and branches, and rises to a greater height: the leaves are ovate-lanceolate, in clusters round the branches, and of a dark green: the flowers are of a middling size, and come out sparingly from between the leaves: the berries are oval, and smaller than those of the first variety, but it is not so hardy as that.

The Portugal Myrtle, which has the leaves much smaller than those of the next, being less than an inch long, and not more than half an inch broad, lanceolate-ovate acute, of a dull green, set pretty close on the branches: the

flowers are smaller, and the berries small and oval.

The Broad-leaved Dutch Myrtle, which has leaves much less than those of the common sort, and more pointed, standing close together on the branches: the midrib on the under side of the leaves is of a purple colour: they are of a darker green, and sit closer to the branches: the flowers are smaller, on shorter peduncles, and come out a little later than those of the common sort.

The Double-flowering Myrtle, which is probably a sub-variety of this; the leaves and growth of the plant, the size of the flowers, and the time of the flowering, agreeing better with this than any of the others.

The Rosemary-leaved or Thyme-leaved Myrtle, which has the branches growing pretty erect; the leaves small, narrow, acute, sessile, and of a lucid green: the flowers are small, appearing late in the season. These varieties are constant; but there are others which are propagated in gardens and nurseries for sale, which are less considerable and more variable, as; the Gold-striped Broad-leaved Myrtle; the Broad leaved Jew's Myrtle, having frequently the leaves in threes; the Gold-striped Orange-leaved Myrtle; the Silver-striped Italian Myrtle; the Striped Box-leaved Myrtle; the Silver-striped Rosemary-leaved Myrtle; the Silver-striped Nutmeg Myrtle; and the Cock's-comb or Bird's-nest Myrtle.

The second species has the branches round, tomentose: the leaves are an inch and half long, elliptic, blunt, above dark and veined, reflex at the edge, the nerves more conspicuous underneath, smooth above, hoary underneath, on very short petioles: the peduncles axillary and terminating, solitary, opposite, tomentose: bractes two, small, oblong, at the base of the calyx, which is turbinate and tomentose, with four rounded segments: the petals oblong, tomentose-hairy without, purple within. It is a native of China, flowering in June and July.

The third rises with a divided trunk to the height of eight or ten feet, sending out many opposite branches covered with a gray bark: the leaves are shorter and rounder at the points, smoother and of a firmer texture than in the ninth sort: the flowers come out from the side of the branches between the leaves, on slender foot-stalks, about an inch in length, two generally from the same point: the berries are round, and brighter than in the ninth: but the leaves and fruit not being aromatic are not in use.

As it retains its leaves, which are of a splendid green, all the year, it makes a good appearance; but the flowers, being small and growing thinly upon the branches, do not make any great figure. It is a native of Jamaica.

VOL. II.

The fourth species has the leaves of a singular structure, being from ovate remarkably attenuated into a lanceolate top: the flowers are five-petalled. It is a native of Surinam.

The fifth has thick leaves: peduncles axillary and terminating, brachiate-panicled, length of the leaves: petals few. Native of America.

The sixth species has a strong upright stalk, covered with a smooth gray bark, dividing towards the top into many slender stiff branches: the leaves are near two inches long, and an inch and quarter broad, of a lucid green, and on very short foot-stalks: the flowers come out at the ends of the branches, several on one common peduncle, which branches out; and each flower stands on a very slender pedicel: they are very like the flowers of the Italian Myrtle. It is a native of Ceylon.

The seventh sort may contend the palm of elegance with most trees. It grows slowly, and flowers late, twice in a year. By age it acquires thickness and height beyond the mediocrity: the trunk is handsome, straight, forming a very lofty thick beautiful pyramidal head: the bark in the younger trees is brown, then ash-coloured, finally white entirely, or with large yellow spots; it is very smooth and even, especially in old trees, but here and there hangs down in slender shreds; the flavour is astringent, not without something of aromatic: the timber very hard, red, compact, ponderous, and capable of being polished; used for the cogs of wheels in the sugar-mills, and other works where considerable friction is required: the younger branches are acutely four-cornered and green: the leaves numerous, quite entire, shining, bright green, with transverse veins, blunt, attenuated into a short petiole; they are always opposite, commonly three or four inches long, of a very sweet aromatic smell, and on account of their agreeable astringency are used for sauce with food: the flowers small, white with a slight tinge of redness: the berries round, the size of peas, crowned with the remains of the calyx, having an aromatic smell and taste, which render them agreeable for culinary purposes. It is a native of the West Indies, where it is sometimes called *Bois d'Inde*.

The eighth species has the whole of the plant smooth: the leaves petioled, an inch long, emarginate, from a reflex margin becoming convex, the upper surface shining very much, veinless, transversely but obliquely marked with dusky nerved lines; the under surface less shining: the younger leaves veined on both sides, with minute raised dots scattered over the under surface, which vanish in the older leaves, and they have dusky spots impressed on the upper

T

surface: the peduncles are purplish, twice as long as the leaves, subracemose, in pairs: the pedicels opposite, commonly four, very remote, three-flowered: the flowers are pedicelled: the calyx is purplish, with roundish segments: the petals oblong, small: the fruit globular, the size of a pepper-corn. It is a native of the West Indies.

The ninth grows to the height of thirty feet or more, in its native state, with a straight trunk, covered with a smooth brown bark, dividing upwards into many branches which come out opposite, garnished with oblong leaves, resembling those of the Bay-tree in form, colour, and texture, but longer, and placed by pairs: when these are bruised or broken, they have a very fine aromatic odour like that of the fruit: the branches grow very regular, so that the trees make a fine appearance, and as they retain their leaves through the year, they are worthy of being propagated for ornament and shade about the habitations of the planters: the flowers are produced in large loose bunches from the side of the branches, towards their ends; each branch is also terminated by a larger bunch than the other; the flowers are small, and of an herbaceous colour. It is a native of the West Indies, flowering in June, July, and August.

The berries are chiefly imported from Jamaica, whence the name Jamaica Pepper; and it is also named All-spice, from a notion of its taste being compounded of several other spices.

It begins to bear fruit in three years after it is planted, but does not arrive at maturity until seven, then often yielding one thousand pounds weight of fruit from an acre.

According to the editor of Miller's Dictionary, "the berries are generally gathered in July in their green state, by twisting off the twigs with the hand, or a pole cleft at one end; and are laid on cloth spread over the barbiques or terraced floors raised a little above the ground, inclosed with an upright ledge of eight or ten inches in height, and divided by transverse partitions into four or more square compartments, that each may contain a day's picking. During the first and second day they are turned often, that the whole may be more exposed to the sun; but when they begin to dry, they are frequently winnowed, and laid in cloths to preserve them better from rain and dews, still exposing them to the sun every day, and removing them under cover every evening, till they are sufficiently dried; which usually happens in ten or twelve days, and is known by the darkness of their complexion, and the rattling of the seeds: they appear at this time wrinkled, and changed to a very dark brown. In this state, being ready for the

market, they are stowed in bags or casks. Some planters also kiln-dry them with great success."

Culture.—The first sort and all the different varieties are capable of being increased by planting cuttings of the strong young shoots of the same year, making them about six inches long, clearing about three inches of the bottom parts, then twisting them and setting them into pots filled with light rich earth, closing it well about them, and watering them to settle it. The pots should then be plunged in the tan hot-bed under glasses, carefully shading them from the sun. This should be done in the beginning of July, or in the early spring. It is likewise useful to cover them close with small glasses.

They may also sometimes be stricken in pots in the natural earth, under a shallow frame and glasses in the summer months, as well as in the open ground in a warm situation.

Slips set out or treated in the same manner as the cuttings, often strike root and produce good plants.

After the plants raised in any of the modes are well rooted and begin to shoot, they should be gradually inured to the open air, so as to be set out in it towards the latter end of August in a warm sheltered situation, being brought under the protection of the green-house in the beginning of autumn, and placed in the less warm parts of it, having free air admitted when the weather will permit. They should be gently watered during the winter, removing any decayed leaves that may appear upon them, and the mould of the pots kept quite clean. The plants also succeed perfectly when placed under a common frame in the winter season, air being freely admitted in fine weather.

In the succeeding spring the plants should be removed carefully with balls of earth about their roots into separate small pots of rich light earth, watering them well at the time, and setting them under a frame, or in the green-house, till perfectly established, when they may be removed into the open air, being placed in a warm aspect.

Towards the beginning of autumn they should be examined, and such plants as have their roots proceeding through the holes in the bottoms of the pots must be removed into others a size larger, loosening the mould and matted roots, afterwards filling the pots up with fresh rich earth, and watering them well. They should then be placed in a sheltered situation, trimming them to a regular figure, and turning them upright, when they have a tendency to be crooked, by proper sticks. When thus carefully trained while in their young growth,

the stems will afterwards continue straight without support.

They are also capable of being increased by layers. All such plants as are furnished with young bottom shoots low enough for laying may have them layed in spring, in the usual way, when they readily emit roots, and become fit to transplant into separate pots in the autumnal season.

And where seed is made use of it should be sown in spring, in pots of light mould, and plunged in a moderate hot-bed: the plants soon come up, which, when two or three inches high, should be potted off separately into small pots, and be managed afterwards as the others.

As the plants advance in growth, some new varieties may perhaps be produced.

Those who raise large quantities of these plants annually, should always keep some strong bushy plants, in order to furnish slips or cuttings for the purpose.

The Double-flowering and Orange-leaved Myrtles are the most difficult to raise by cuttings; and the last sort, and those with variegated leaves, are more tender than the others.

The common Broad-leaved, and Broad-leaved Dutch, as well as the Portugal sorts, succeed in the open ground in warm situations and dry soils.

Where they are intended to have bushy heads, the lower shoots should be trimmed off, and the plants only suffered to branch out at the top in different directions, so as to form handsome heads. Those which are designed to be shrubby, should have their lateral branches encouraged so that they may be well feathered from the top to the bottom. They should afterwards in general be left to take their own natural growth, except just taking off the rambling shoots. When their heads become thin and straggling, those shoots which are proper for sending out new shoots to fill up the vacancies and produce regularly should be shortened by the knife.

The practice of clipping the shrubs with garden-shears into globes, pyramids, &c., as is sometimes done, is very injurious; the necessary trimming should always be performed with the knife, and that only as above, as the plants appear to the most advantage when they grow naturally.

When the heads of the plants become very irregular, or thin and stubby, they may be renewed by heading down all the branches pretty short in spring, and shifting them into larger pots of fresh mould, with the balls of earth about their roots, giving plenty of water during summer, when they will branch out again finely, and form handsome full heads.

In respect to the general culture, as the plants advance in stature they should annually be removed into larger pots, according to the size of their roots; but care should be taken not to put them into pots too large, which causes them to shoot weak, and sometimes proves the destruction of them. When they are taken out of the former pots, the earth about their roots should be pared off, and that withinside the ball gently loosened, that the roots may not be too closely confined; and then often replace them in the same pots, when not too small, filling up the sides and bottom with fresh rich earth, and giving them plenty of water to settle the earth to their roots; which should be frequently repeated, as they require to be often watered both in winter and summer, and in hot weather they should have it in large quantities.

The proper season for shifting these plants is in April and August; for, if it be done much sooner in the spring, the plants are in a slow growing state, and not capable to strike out fresh roots again quickly; and when done later in autumn, the cold weather coming on prevents their taking root.

In the autumn, when the nights begin to be frosty, the plants should be removed into the green-house; but when the weather proves favourable they may remain abroad until the beginning of November; for, if they are carried into the green-house too soon, and the autumn should prove warm, they make fresh shoots at that season, which are weak, and often grow mouldy in winter. When the weather is so severe as to require the windows to be kept closely shut, they are often also greatly defaced; on which account they should always be kept as long abroad as the weather will permit, and be removed out again in the spring before they shoot out; and while they are in the green-house should have as much free air as possible when the weather is mild and proper for the purpose.

The tender kinds are mostly increased by seeds; but when any of them are pretty branchy, they may also be tried by layers and cuttings. And the eighth sort succeeds best in this way.

The seed should be procured from abroad, preserved in sand, &c., and be sown in spring in pots of fresh mould, plunging them in the bark-bed: the plants come up the same season; which, when two or three inches in height, should be planted out in separate small pots, and plunged in the bark-bed, supplying them with water, and managing them as other woody plants of the same kind.

As the second sort often branches out low, some of the young shoots may be layed in spring, by slit-laying or wiring, plunging the pots in

which they are layed in the tan-bed; when they will probably be well rooted in one year, though it is sometimes two before they strike good root, when they should be potted off into separate pots and managed as the others.

The last sort is best raised in this way.

The cuttings of some of the short young shoots should be made from such of the plants as afford them; planting them in pots of fresh compost in July, plunging them in the bark-bed, and covering them close with a low hand glass, giving due water.

They mostly take good root the same year, and are fit to plant out in separate small pots in the following spring.

The general management of these sorts is

only that of keeping them always in the stove, except a month in the heat of summer, when they may be set out in the open air. They should be suffered to shoot nearly in their own way, keeping them, however, to upright stems, and allowing their heads to branch out according to nature, except just reducing the very irregular branches, giving frequent waterings in common with other woody plants of the same kind, and shifting them occasionally into larger pots.

The first sort and varieties are highly ornamental plants for the borders and green-house, and the other tender sorts in the stove collections.

N A P

NAPÆA, a genus containing plants of the hardy herbaceous flowery perennial kind.

It belongs to the class and order *Diœcia Monadelphica* (*Monadelphica Polyandria*), and ranks in the natural order of *Columniferae*.

The characters are: that in the male the calyx is a bell-shaped five-cleft perianthium, round, permanent: the corolla has five oblong petals, concave, patulous, convex with oblong claws: the stamina have very many capillary filaments, of a middling length, connected in a column: anthers roundish, compressed: the pistillum is a conical germ, minute: style cylindric, ten-cleft, capillary: stigmas none: the pericarpium abortient: female on a distinct individual: the calyx and corolla as in the male: the stamina have filaments as in the male, but shorter: anthers small, effete: the pistillum is a conical germ: style as in the male, longer than the stamens: stigmas blunt: the pericarpium has ten capsules, converging into an ovate form, sharpish, awnless: the seeds are solitary, and kidney-form.

The species cultivated are: 1. *N. laevis*, Smooth Napæa; 2. *N. scabra*, Rough Napæa.

The first has a perennial root, frequently creeping: the stems smooth, about four feet high: the leaves alternate, upon pretty long slender foot-stalks, deeply cut into three lobes, which end in acute points, and are regularly serrate; those on the lower part of the stem are near four inches long, and almost as much in

N A P

breadth, but they diminish gradually to the top of the stem. At the base of the leaf comes out the peduncle, about three inches long, dividing at top into three smaller, each sustaining one white flower, smaller than in the second sort, with a longer column of stamens, the anthers standing out beyond the corolla. It is a native of Virginia.

The second has also a perennial root, composed of many thick fleshy fibres, striking deep into the ground, and connected at the top into a large head, from which come out many rough hairy leaves, near a foot diameter each way, deeply cut into six or seven lobes, irregularly indented on their edges, each lobe having a strong midrib, all meeting at the foot-stalk, which is large and long, arising immediately from the root: the flower-stalks seven or eight feet high, dividing into smaller branches, having one leaf at each joint, of the same form as those below, but diminishing in size towards the top, where they seldom have more than three lobes, which are divided to the foot-stalk. Towards the upper part of the stalk comes out from the side at each joint a long peduncle, branching out towards the top, and sustaining several white flowers, which are tubulous at bottom where the segments of the petal are connected, but spread open above, and are divided into five obtuse segments: the male plants are barren; but in the female plants the flowers are succeeded by ten capsules, placed in a ring, semicircular, finishing at top in a re-

curved dagger-point, compressed wedge-shaped, convex on the back, with a raised line along the middle, flat at the sides and subcrenulate towards the dorsal margin, one-celled, valveless, or sometimes but seldom opening by two valves: the flowers are in heads, and the fruit orbicular, depressed, consisting of eight or ten joints. It is also a native of Virginia.

Culture.—These plants are easily increased by seeds, which should be sown on a bed of common earth in the spring, keeping them clear from weeds till autumn, and then transplanting them where they are to remain. They succeed best in a rich moist soil, in which they will grow very luxuriantly, and must be allowed room.

The first sort may also be increased by parting the roots, and planting them out where they are to remain in the autumn.

They afford variety among other plants in the borders.

NAPELLUS. See ACONITUM.

NAPO-BRASSICA. See BRASSICA.

NAPUS. See BRASSICA.

NARCISSO-LEUCOIUM. See LEUCOIUM.

NARCISSUS, a genus containing plants of the bulbous-rooted perennial flowering kind.

It belongs to the class and order *Hexandria Monogynia*, and ranks in the natural order of *Spathaceæ*.

The characters are: that the calyx is an oblong spathe, obtuse, compressed, opening on the flat side, shrivelling: the corolla has six ovate, acuminate petals, flat, equal, inserted into the tube of the nectary externally above the base; nectary one-leafed, cylindric-funnel-form, coloured on the border: the stamina have six awl-shaped filaments, fixed to the tube of the nectary, shorter than the nectary: anthers oblongish: the pistillum is a roundish germ, obtusely three-sided, inferior: style filiform, longer than the stamens: stigma bifid, concave, obtuse: the pericarpium is a roundish capsule, obtusely three-cornered, three-celled, three-valved: the seeds are many, globular, and appendicled.

The species cultivated are: 1. *N. pseudo-narcissus*, Common Daffodil; 2. *N. poeticus*, Poetic, or White Narcissus; 3. *N. biflorus*, Two-flowered Narcissus, or Pale Daffodil; 4. *N. bicolor*, Two-coloured Narcissus; 5. *N. minor*, Least Daffodil; 6. *N. triandrus*, Rush-leaved Narcissus, or Reflexed Daffodil; 7. *N. orientalis*, Oriental Narcissus; 8. *N. Bulbocodium*, Hoop-Petticoat Narcissus; 9. *N. tazetta*, Polyanthus Narcissus; 10. *N. serotinus*, Late-flowering Narcissus; 11. *N. odoratus*, Sweet-scented Narcissus, or Great Jonquil; 12. *N. calathinus*, Calathine Yellow Narcissus; 13. *N. jonquilla*, Common Jonquil.

The first has a large bulbous root, from which

come out five or six flat leaves, about a foot long, and an inch broad, of a grayish colour, and a little hollow in the middle like the keel of a boat: the stalk rises a foot and half high, having two sharp longitudinal angles; at the top comes out one nodding flower, inclosed in a thin spathe: the corolla is of one petal, being connected at the base, but cut almost to the bottom into six spreading parts; in the middle is a bell-shaped nectary, called by gardeners the cup, which is equal in length to the petal, and stands erect: the petal is of a pale brimstone or straw colour, and the nectary is of a full yellow: the seeds are roundish, black. It is a native of many parts of Europe, flowering in March.

There are varieties with white petals and a pale yellow cup, with yellow petals and a golden cup, with a double flower; with three or four cups within each other; Tradescant's large double; long-tubed flowered; short-tubed; dwarf-stalked; and the peerless Daffodil.

Many other varieties have likewise been noticed by writers.

The second species has a smaller and rounder bulb than the first: the leaves are longer, narrower, and flatter: the stalk or scape does not rise higher than the leaves, which are of a gray colour: at the top of the stalk comes out one flower from the spathe, nodding on one side: the corolla snow white, spreading open flat, the petals rounded at the points: the nectary or cup in the centre is very short, and fringed on the border with a bright purple circle: the flowers have an agreeable odour, appear in May, and seldom produce seeds. It is a native of Italy, &c. flowering in April.

There are varieties with double white flowers, with purple-cupped flowers, and with yellow-cupped flowers.

The third usually produces two flowers: it frequently occurs, however, with one, more rarely with three; in a high state of culture it probably may be found with more. When it has only one flower, it may easily be mistaken for one of the varieties of the second sort, but may be distinguished from it by the petals being of a yellowish hue, or rather a pale cream colour; the nectary wholly yellow, not having the orange or crimson rim, and by its flowering at least three weeks earlier; the top also of the flowering stem very soon after it emerges from the ground bends down and becomes elbowed; whereas in that it continues upright till within a short time of the flower's expanding. It is a native of several parts of Europe, flowering in May.

There are two or three varieties, as with sulphur-coloured flowers, and with white reflexed petals, with gold-coloured borders.

The fourth species resembles the first; but

the petals are white, the nectary is dark yellow and larger, with a spreading, waved, notched border. Gouan thinks it is easily distinguished by its leaves, which are scarcely a palm in length and half an inch in breadth; by its large flower, with cordate-ovate petals, imbricate at the base, and sulphur-coloured, and by the nectary having a reflex mouth, twelve-cleft or thereabouts, the lobes also being toothed and curled: the scape is the length of the leaves, or a little shorter, and thick. It is a native of the South of Europe, flowering in April and May.

There is a large variety, which approaches in its general appearance very near to the first sort; but it is a much taller plant, and has its leaves more twisted, as well as more glaucous: the flower, but especially the nectary, is much larger, and the petals are more spreading. It is of a fine deep yellow colour, having sub-varieties with double flowers, and is a native of Spain, flowering in April. It is sometimes known by the title of Great Yellow *Spanish-Bastard Daffodil*.

The fifth is nearly related to the first sort, but is three times smaller in all its parts: the scape is scarcely striated: the spathe is greenish: the flowers more nodding: the petals distinct at the base, lanceolate, straight, not oblique or ovate: the margin of the nectary six-cleft, waved, curled. But though the flowers are not so large as those of the other species, when the roots are planted in a cluster, they make a very pretty show, and have this advantage, that they flower somewhat earlier than any of the others. It is a native of Spain.

The sixth is of the same size with the second, but the leaves are narrower by half and channelled: the spathe one-flowered: the whole corolla snow-white: the petals ovate-oblong: the nectary bell-shaped, shorter by half than the corolla, with the margin straight, and unequally crenulate: the stamens three, seldom six: the anthers dark yellow, shorter than the nectary. In nurseries the flowers are of a pale yellow, having two and sometimes three flowers from a spathe. It is a native of Portugal.

There are varieties with cup and petals wholly of a gold colour; with yellow with a white cup; and with white, with a yellow cup.

The seventh species is broad-leaved, having the appearance of the ninth sort: the corolla is white: the nectary erect, half or one-third of the length of the petals, trifid, yellow, with the lobes emarginate. It is a native of the Levant, flowering in May.

There are several varieties.

The eighth has small bulbs: the leaves very narrow, having some resemblance to those of the Rush, but a little compressed, with a longi-

tudinal furrow on one side; they are seldom more than eight or nine inches long: the flower-stalk slender, taper, about six inches long: petal scarce half an inch long, cut into six acute segments: the nectary or cup is more than two inches long, very broad at the brim, lessening gradually to the base, formed somewhat like the old farthingale or bell-hoop petticoat worn by the ladies. It is a native of Portugal, flowering in April or May.

The ninth species has a large, roundish bulb: the leaves three or four, long, narrow, plane: the scape or flower-stalk upright, broadish, angular, concave, from ten or twelve to eighteen inches in height: the flowers six or seven to ten from one spathe, very fragrant, clustered, white or yellow. It is a native of Spain and Portugal, &c., flowering in February and March.

There are a great many varieties: the principal of which are; with yellow petals, with orange, yellow, or sulphur-coloured cups or nectaries; with white petals, with orange, yellow, or sulphur-coloured cups or nectaries; with white petals, with white cups or nectaries; and with double flowers of the different varieties.

The flower catalogues contain about a hundred sub-varieties under these heads. It may be observed, that "the varieties with white petals and white cups are not so much esteemed as the others; there are, however, two or three with large bunches of small white flowers, which are valuable for their agreeable odour, and for flowering later than most of the others. There is also one with very double flowers, the outer petals white, those in the middle some white, others orange-coloured," which "has a very agreeable scent, flowers early, and is generally called the *Cyprus Narcissus*," and is the most beautiful of all the varieties when blown in glasses in rooms or other places.

The tenth has a small bulb: the leaves few, narrow: the stalk jointed, nine inches high: the corolla white, cut into six narrow segments: the cup yellow. It flowers late in the autumn, and is a native of Spain, Italy, and Barbary.

The eleventh species has the flower deep yellow, three times as large as that of the ninth, sometimes one only from a spathe, but frequently more: the nectary not fringed, but divided at the mouth into six blunt lobes. It possesses more fragrance than many of the others. It is a native of the South of Europe, flowering in April and May.

It varies with double flowers.

The twelfth resembles the ninth very much, but the petals are a little larger and sharper; the nectary is the same length with the petal: the leaves two or three, a foot or more in length: the stem is slender, strong, a foot in length: the

flowers two or three from a spathe, very elegant, large and loose: the petals yellow: the cup half an inch long, sinuated at the edge, of a deeper yellow colour. It flowers in April, and is a native of the southern parts of Europe and of the Levant.

The thirteenth is named from the narrowness of its leaves, like those of Rushes; there are two or three of them usually on a plant, and they are angular, fleshy, and almost round: the scape is round, hollow, producing at top from three to five flowers from a spathe, sometimes no more than two, very fragrant petals orbiculate or mucronate, both they and the cup yellow: the bulb small, white, covered with dark membranes. It is a native of Spain, flowering in April and May.

It varies with double flowers.

Culture.—All these different species and varieties may be increased with facility, by planting the off-set bulbs from the roots; and by sowing the seed in order to procure new varieties, which is chiefly practised for the fine sorts of *Polyanthus Narcissus*.

For this last purpose the seed should be carefully saved from the best and most curious plants after being perfectly ripened.

The seed should be sown soon after it becomes ripe, as about the beginning of August, in shallow boxes or flat pans perforated with holes in the bottoms, and filled with fresh light sandy earth, being covered about a quarter of an inch deep with fine sifted mould, and placed in such situations as are only exposed to the morning sun, till the beginning of winter, when they should be removed to have the full sun, and be sheltered from severe weather. In the spring, when the plants appear, they should be occasionally watered in dry weather, and be screened from the mid-day heat, removing them into cooler situations as the warm season advances, keeping them free from all sorts of weeds. Towards the latter end of the summer, when their stems decay, the surface mould of the boxes or pans should be stirred or wholly removed, and some fresh mould sifted over the plants, being careful not to disturb the roots, and keeping them rather dry in a shaded place.

They should have the same management annually, till the period of their leaves decaying in the third summer, when the bulbs should be taken up, and the largest separated and planted out on raised beds of light fine mould, in rows six inches apart, and three or four distant in them, having the depth of two or three inches. The smaller bulbs may be covered in on another bed with fine mould, to

remain till of sufficient size to be planted out as above.

They should afterwards be kept clean; and when they show flowers so as to ascertain their properties, they may be removed, and managed in the manner directed below.

The off-set bulbs of the old plants, especially the double sorts, should be separated from the roots annually, or at furthest every two or three years, in the latter part of the summer, when their leaves and stems decay, planting their larger bulbs out at different times, from the end of August to the beginning of November, in order to afford variety; but the earlier they are planted the stronger they blow. When left out of the ground till February, or later, they mostly appear weak.

They succeed best where the soil is of a light, dry, fresh, hazel, loamy quality, and the aspect south-easterly; as where inclined to moisture they are very apt to be destroyed.

They afterwards only require to be kept free from weeds, and to have the ground stirred above them in the autumn.

The small bulbs may be planted out in rows in nursery-beds to increase for being planted out in the same manner.

When these roots are planted in the open borders or other places, in assemblage with other bulbous flowers, they should be deposited in little patches, about three or four roots in each, putting them in with a blunt dibble, or holing them in with a garden-trowel, three or four inches deep; in which mode they display their flowers more conspicuously than when planted singly.

Where a large quantity are planted out alone in beds in order to exhibit a full bloom, as often practised with the fine *Polyanthus-Narcissus*, Jonquils, &c. the beds should be four feet wide, with foot-and-half or two-feet wide alleys between them; in these beds the roots should be planted in rows length-ways, nine inches asunder, either with a blunt dibble or with a hoe, three or four inches deep, and six distant in each row, covering them evenly with the earth, and raking the surface smooth.

In order to blow the *Polyanthus-Narcissus* and Jonquil in the highest perfection, curious florists often bestow particular care in their culture: some, preparing beds of compost, as for the fine Hyacinths, &c. managing them in the same manner. But they succeed well in beds of light dry mould.

Where the bulbs of this sort are intended for sale, they should be lifted at furthest every two years, to prevent their becoming flattened by pressure, and of course less valuable.

The bulbs may be retained out of the ground

two or three months where it is necessary; but it is better to replant them as above.

Culture in Glasses.—It is sometimes the practice to cultivate the *Polyanthus Narcissus* and some of the large Jonquil kind in glasses in rooms, in order to blow in the winter or early spring season. For this purpose dry firm bulbs should be chosen, and one placed in each single glass or bottle provided for the purpose, any time from October till the spring, being then filled up to the roots of the bulbs with soft water, and deposited in a light warm place: in this method the plants soon begin to grow, and send forth flower-stems, affording good flowers, which have a very ornamental appearance.

The principal circumstances to be regarded in this management are, those of keeping the glasses well supplied with fresh portions of water, so as constantly to be up to the lower part of the roots, and changing the whole, so as to keep it always in a pure state.

They may likewise be raised in pots filled with light sandy mould, and placed in the same situations.

Also in hot-houses, they may be made to blow early, when kept either in pots or glasses.

When planted out in the manner mentioned above, in the borders, clumps, and other parts of pleasure-grounds, they are most of them highly ornamental, producing much variety in the early spring months.

All the different principal sorts may be procured from the seeds-men in London, who import them for sale from Holland, where they are raised in large quantities.

NEPETA, a genus containing plants of the herbaceous perennial kind.

It belongs to the class and order *Didynamia Gymnospermia*, and ranks in the natural order of *Verticillatæ*.

The characters are: that the calyx is a one-leaved perianthium, tubular, cylindric: mouth five-toothed, acute, erect: upper toothless longer; lower more spreading: the corolla is one-petalled, ringent: tube cylindric, curved inwards: border gaping, opening, spreading, cordate, ending in two reflex blunt very short segments: upper lip erect, roundish, emarginate; lower roundish, concave, larger, entire, crenulate: the stamina have four awl-shaped filaments beneath the upper lip, approximating, two of them

shorter: anthers incumbent: the pistillum is a four-cleft germ: style filiform, length and situation of the stamens: stigma bifid, acute: there is no pericarpium: calyx straight, containing the seeds in its bosom: the seeds four, and sub-ovate.

The species cultivated are: 1. *N. cataria*, Common Catmint; 2. *N. Pannonica*, Hungarian Catmint; 3. *N. nuda*, Naked or Spanish Catmint; 4. *N. Italica*, Italian Catmint; 5. *N. tuberosa*, Tuberous-rooted Catmint.

The first has a perennial root, from which arise many branching stalks, two feet high and more, upright, pubescent: the leaves are of a velvet-like softness, wrinkled, ash-coloured or hoary, particularly underneath: spikes composed of interrupted whorls terminate the stem, and come out in branches from the axils of the leaves: the flowers are subsessile, and separated at the base by a small lanceolate bracte: the calyx downy with green ribs: the corolla white, with a tinge of red, and spotted with purple: the whole plant has a strong scent between Mint and Pennyroyal. It is called Catmint, from cats being very fond of it. It is a native of most parts of Europe, flowering from July to September.

The second species has a perennial root, branched, woody, the size of a quill or more, brown on the outside, knobbed at the end: the stems several, from three to four feet in height, grooved, smoothish, with opposite branches forming a panicle: the leaves oblong, blunt, scarcely cordate, bluntly serrate, smooth, the lower ones on longer petioles, the upper ones on very short ones; they are successively smaller as they approach the racemes, till they become so small that the ends of the racemes seem to be leafless: the racemes are axillary and opposite, containing about twenty flowers: the bractes almost bristle-shaped: the calyx somewhat villose and striated: the corolla more or less red; in the cultivated plant very deep, and elegantly dotted. It is a native of Hungary, &c., flowering from August to October.

The third has the stems two feet high, smooth, strict, four-grooved; the older ones dark purple: the leaves blunt, veined, naked, rugged on both sides: the racemes brachiate: the bractes linear: the flowers distinct: the corollas whitish-rufoescent, with the beard of the palate white, and the throat dotted with purple. According to Haller, the flowers are blue and white. It is a native of the South of Europe, flowering from June to August.

In the fourth species, the stalks seldom rise more than a foot and half high, sending out very few branches: the whorls of flowers

 Trailing *Nolana*

which form the spike are distant from each other, and sit close to the stalk: the leaves short, oval, heart-shaped: the plant is hoary and strong scented. It is a native of Italy, flowering from June to August.

The fifth has a thick knobbed root, from which come out one or two stalks, that often decline to the ground; they are about two feet and a half long, and send out two side branches opposite: the leaves are oblong, crenate, sessile, deep green: the upper part of the stalk, for more than a foot in length, has whorls of flowers, the lower ones two inches asunder, but nearer all the way up; they sit very close to the stalks, and are guarded by small bractes: the corolla is blue. It is a native of Spain and Portugal, flowering from June to August.

Culture.—These plants are capable of being increased by seeds, parting the roots, slips, and cuttings, but the first is the principal mode.

The seeds may be sown in the autumn or spring, on a bed of light earth, raking it in lightly: when the plants have attained some growth, they may be planted out in nursery rows, to remain till the autumn, when they may be set out where they are to remain; or they may remain where sown, only thinning them properly out.

The partings of the roots may be set out separately, where they are to remain, in the beginning of the autumn, or spring, being afterwards kept free from weeds.

Slips or cuttings of the branches may be planted out in the spring in shady situations, occasional supplies of water being given till they have stricken root.

The first sort and varieties, as well as many of the others, may afford variety in the borders, clumps, and other parts of pleasure-grounds, in mixture with herbaceous plants of different descriptions. They are likewise some of them cultivated for medicinal use.

NERIUM, a genus comprehending plants of the evergreen flowering shrubby kind.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Contortæ*.

The characters are: that the calyx is a five-parted perianthium, acute, very small, permanent: the corolla is one-petalled, funnel-form: tube cylindric, shorter than the border: border very large, five-parted; segments wide, blunt, oblique: nectary a crown terminating the tube, short, lacerated into capillary segments: the stamina have five, awl-shaped filaments, very short, in the tube of the corolla: anthers sagittate, converging, terminated by a long thread: the pistillum a roundish germ, bifid: style cy-

Vol. II.

lindric, the length of the tube: stigma truncate, sitting on an orblet, fastened to the anthers: the pericarpium has two follicles, round, long, acuminate, erect, one-valved, opening longitudinally: the seeds numerous, oblong, crowned with down, placed imbricately.

The species cultivated are: 1. *N. oleander*, Common Rosebay, or Oleander; 2. *N. odorum*, Sweet-Scented Rosebay, or Oleander; 3. *N. antidysentericum*, Oval-Leaved Rosebay; 4. *N. coronarium*, Broad-Leaved Rosebay.

The first rises with several stalks to the height of eight or ten feet: the branches come out by threes round the principal stalks, and have a smooth bark, which in that with red flowers is of a purplish colour, but in that with white flowers of a light green: the leaves for the most part stand by threes round the stalks, upon very short footstalks, and point upwards; they are three or four inches long, and three quarters of an inch broad in the middle, of a dark green, very stiff, and end in acute points: the flowers come out at the end of the branches in large loose bunches, and are of a bright purple, or crimson colour, or of a dirty white. It is a native of the Levant, flowering in July and August.

In warm dry summers this plant makes a fine appearance, the flowers then opening in great plenty; but in cold moist seasons the flowers often decay without expanding, unless the plants are placed in a green-house or under a glass-case.

The variety with white flowers is the most tender; but there are others, as the Stripe-leaved; the Broad-leaved Double-flowered, the Striped Double-flowered, and with different shades of red from purple to crimson or scarlet.

The second species rises with shrubby stalks six or seven feet high, covered with a brown bark: the leaves are stiff, from three to four inches long, and not more than a quarter of an inch broad, of a light green, and the edges reflexed; they are opposite, or alternate, or by threes round the branches: the flowers are produced in loose bunches at the ends of the branches; they are of a pale red, and have an agreeable musky scent. It grows naturally in India, flowering from June to August.

There is a variety with leaves six inches long, and one inch broad in the middle, of a much thinner texture than those of the first, and their ends are generally reflexed; they are of a light green, and irregularly placed on the branches by pairs, alternately, or by threes: the flowers are produced in very large bunches at the end of the branches, upon long peduncles; they have three or four rows of petals one within another: they are much larger than those of the common

U

sort, and smell like those of hawthorn: the plain flowers are of a soft red or peach colour; but in most they are beautifully variegated with a deeper red, and make a fine appearance: the usual time of flowering is in July and August, but in a warm stove it will continue in flower till Michaelmas: from the flowers being double, they are not succeeded by seeds. They are all supposed to have a poisonous quality.

The third is a middle sized tree, with brachiate branches: the leaves opposite, flat, quite entire, smooth: the flowers herbaceous or greenish white, in short subterminating racemes: the segments of the crown oblong, alternately trifid and linear. It is a native of the East Indies.

The fourth species is an elegant branched shrub, four feet high, milky, with an ash-coloured bark: the younger branches are shining, green, compressed a little, opposite at the end: the leaves long, lanceolate, acute, quite entire, shining, on short petioles, opposite: the peduncles one-flowered, thickish, in pairs from the divisions of the branchlets and decussating with them: the flowers handsome, but without scent: the perianthium green: tube of the corolla greenish yellow: the border snow-white. It is a native of the East Indies, flowering most part of the summer.

Culture.—These plants may be increased by layers, cuttings, and suckers from the roots.

The layers should be made in the early spring months, as from March till May, but the earlier the better; the youngest lower branches being chosen for the purpose, which should be slit-layed, giving plenty of water during the summer, and they will be mostly rooted by the autumn following; but by plunging the pots in which they are layed in a bark hot-bed their rooting may be greatly forwarded: when they are properly rooted, they may be taken off and removed into separate pots.

The cuttings should be planted in the spring or the early part of summer, taking off the young shoots, five or six inches long, and planting them in large pots of rich mould, placing them under glasses, and giving water and shade occasionally: but if plunged in a bark-bed it will greatly promote and forward their rooting.

The suckers arising from the bottom are sometimes furnished with roots, but when this is not the case a small slit should be given at the lowest part; afterwards applying fresh mould around it, when fibres will be emitted by the end of summer; they may then be taken off and potted separately.

The first sort and varieties is rather hardy, but should be kept constantly in pots or tubs, to be protected through severe winters.

The other sorts are often placed in the hot-house during winter, but when less tenderly treated and supplied more freely with air in mild weather, they are said by some to succeed better, provided they be carefully screened from every effect of frost or severe cold.

They are very ornamental among other potted plants of the less tender kinds.

NETTLE-TREE. See *CELTIS*.

NEW JERSEY TEA. See *CEANOTHUS*.

NICKER TREE. See *GUILANDINA*.

NICOTIANA, a genus containing plants of the herbaceous annual kind.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Luridae*.

The characters are: that the calyx is a one-leaved perianthium, ovate, half-five-cleft, permanent: the corolla is one-petalled, funnel-form: tube longer than the calyx: border somewhat spreading, half-five-cleft, in five folds: the stamina have five awl-shaped filaments, almost the length of the corolla, ascending: anthers oblong: the pistillum is an ovate germ: style filiform, the length of the corolla: stigma capitate, emarginate: the pericarpium is a subovate capsule, marked with a line on each side, two-celled, two-valved, opening at top: receptacles half-ovate, dotted, fastened to the partition: the seeds numerous, kidney-form, wrinkled.

The species cultivated are: 1. *N. fruticosa*, Shrubby Tobacco; 2. *N. Tabacum*, Virginian Tobacco; 3. *N. rustica*, Common or English Tobacco.

The first rises with very branching stalks about five feet high: the lower leaves a foot and half long, broad at the base where they half embrace the stalks, and about three inches broad in the middle, terminating in long acute points: the stalks divide into many smaller branches, terminated by loose bunches of flowers of a bright purple colour, succeeded by acute-pointed seed-vessels. It was found at the Cape.

There is a variety which rises about five feet high: the stalk does not branch so much as that of the former: the leaves are large and oval, about fifteen inches long and two broad in the middle, but diminish gradually in size to the top of the stalk, and with their base half embrace it: the flowers grow in closer bunches than those of the former, and are white: they are succeeded by short, oval, obtuse seed-vessels. It flowers about the same time with the former, and grows naturally in the woods of the island of Tobago.

The second species has a large, long, annual root; an upright, strong, round, hairy stalk, branching towards the top; leaves numerous, large, pointed, entire, veined, viscid, pale green;

bractes long, linear, pointed: the flowers in loose clusters or panicles: the calyx hairy, about half the length of the corolla, cut into five narrow segments: tube of the corolla hairy, gradually swelling towards the border, where it divides into five folding acute segments of a reddish colour. It is a native of Virginia.

There are several varieties; as the great broad-leaved, in which the leaves are more than a foot and a half long, and a foot broad, their surfaces very rough and glutinous, and their bases half embrace the stalk. In a rich moist soil the stalks are more than ten feet high, and the upper part divides into smaller branches, which are terminated by loose bunches of flowers standing erect: they have pretty long tubes, and are of a pale purplish colour. It flowers in July and August, and is the sort commonly brought to market in pots, being sometimes called *Oronoko Tobacco*.

There is another, in which the stalks seldom rise more than five or six feet high, and divide into more branches. The leaves are about ten inches long and three and a half broad, smooth, acute, sessile; the flowers are rather larger, and of a brighter purple colour. It flowers at the same time; and is called by some *Sweet-scented Tobacco*.

The narrow-leaved rises with an upright branching stalk, four or five feet high. The lower leaves are a foot long, and three or four inches broad: those on the stalks are much narrower, lessening to the top, and end in very acute points, sitting close to the stalks; they are very glutinous. The flowers grow in loose bunches at the top of the stalks; they have long tubes, and are of a bright purple or red colour. They appear at the same time with the former.—These varieties are also all natives of America.

The third has the stalks seldom rising more than three feet high: the leaves smooth, alternate, upon short footstalks: the flowers in small loose bunches on the top of the stalks, of an herbaceous yellow colour, appearing in July. It is commonly called *English Tobacco*, from its having been the first introduced here, and being much more hardy than the other sorts. It came originally from America, under the name of *Petum*.

There is a variety which rises with a strong stalk near four feet high; the leaves are shaped like those of the preceding, but are greatly furrowed on their surface, and near twice the size, of a darker green, and on longer footstalks. The flowers are of the same shape, but larger.

Culture.—The two first sorts may be increased by sowing the seeds annually in the spring,

as March, on a hot-bed, the last in the natural ground.

The seeds should be covered about a quarter of an inch deep; and when the plants are come up they should be allowed fresh air daily, and occasional waterings, managing them as tender annuals. When the plants are from three to six inches high, as in May or the following month, they should be planted out in moist weather, in the open ground; such as are designed for ornament, singly, and those intended for use, in rows, any where, three feet asunder; giving a good watering as soon as planted, repeating it occasionally till the plants have got fresh root.

The second species may also be raised by sowing the seeds in a warm border in April, for setting out in the same manner, or by sowing in patches in the flower borders, &c. to remain, thinning the plants afterwards to one in each patch.

In the third sort the seeds may be sown in any bed or border in the spring, raking them in lightly. When the plants are three inches high, they should be planted out where they are to remain; or they may be sown in patches to remain, thinning the plants out afterwards as above.

In America, where regular plantations are made, the method is this:

“The beds being prepared and well turned up with the hoe, the seed, on account of its smallness, is mixed with ashes, and sown upon them, a little before the rainy season. The beds are raked, or trampled with the feet, to make the seed take the sooner. The plants appear in two or three weeks. As soon as they have acquired four leaves, the strongest are drawn up carefully, and planted in the field by a line, at the distance of about three feet from each plant. If no rain fall, they should be watered two or three times. Every morning and evening the plants must be looked over, in order to destroy a worm which sometimes invades the bud. When they are about four or five inches high they are to be cleaned from weeds and moulded up. As soon as they have eight or nine leaves, and are ready to put forth a stalk, the top is nipped off, in order to make the leaves longer and thicker. After this the buds which sprout at the joints of the leaves are all plucked, and not a day is suffered to pass without examining the leaves, to destroy a large caterpillar which is sometimes very destructive to them. When they are fit for cutting, which is known by the brittleness of the leaves, they are cut with a knife close to the ground; and, after lying some time, are carried to the drying

shed or house, where the plants are hung up by pairs, upon lines, leaving a space between that they may not touch one another. In this state they may remain to sweat and dry. When perfectly dry, the leaves are stripped from the stalks, and made into small bundles tied with one of the leaves. These bundles are laid in heaps, and covered with blankets. Care is taken not to overheat them, for which reason the heaps are laid open to the air from time to time and spread abroad. This operation is repeated till no more heat is perceived in the heaps, and the Tobacco is then stowed in casks for exportation." But, "In China, where the use of tobacco both in snuff and for smoking is very general, buildings are not thought necessary, according to sir George Staunton, as they are in the West Indies, for curing it; there being little apprehension of rain to injure the leaves when plucked. They are hung on cords to dry without any shelter, upon the spot in which they grew."

It is probable that this plant might be grown with advantage in this climate if it were not prohibited.

These sorts, when cultivated for the purpose of ornament, produce a fine effect by their leaves and flowers in the autumn, and also afford much variety.

NIGELLA, a genus containing plants of the hardy herbaceous flowering annual kind.

It belongs to the class and order *Polyandria Pentagynia*, and ranks in the natural order of *Multisiliquæ*.

The characters are: that there is no calyx: the corolla has five petals, ovate, flat, blunt, spreading, more contracted at the base: the nectaries eight, placed in a ring, very short; each two-lipped; outer lip larger, lower, bifid, flat, convex, marked with two dots; inner lip shorter, narrower, from ovate ending in a line: the stamens have numerous awl-shaped filaments, shorter than the petals. Anthers compressed, blunt, erect: the pistillum has several germs (five to ten), oblong, convex, compressed; erect, ending in styles which are awl-shaped, angular, very long, but revolute, permanent: stigmas longitudinal, adnate: the pericarpium capsules as many, oblong, compressed, acuminate, connected on the inside by the suture, gaping on the inside at top: the seeds very many, angular, and rugged.

The species cultivated are: 1. *N. damascena*, Common Fennel-flower; 2. *N. saliva*, Small Fennel-flower; 3. *N. arvensis*, Field Fennel-flower; 4. *N. Hispanica*, Spanish Fennel-flower; 5. *N. orientalis*, Yellow Fennel-flower.

The first rises with an upright branching stalk a foot and a half high: the leaves much longer and finer than those of the third: the flowers are large, pale blue, with a five-leaved involucre under each, longer than the flower; they are succeeded by larger swelling seed-vessels, with five horns at the top. It is a native of the South of Europe, flowering from June to September.

From the fine cut leaves about the flower, it has the names of *Fennel-flower*, *Devil-in-a-bush*, and *Love-in-a-mist*; but the first is become obsolete.

There is a variety with single white flowers, and another with double flowers, which is frequently cultivated in gardens with other annuals for ornament.

The second species rises to the same height as the preceding: the leaves are not so finely cut, and are a little hairy: at the top of each stalk is one flower, composed of five white petals, which are slightly cut at their end into three points; these are succeeded by oblong swelling seed-vessels with five horns at the top, filled with small pale-coloured seeds. It is a native of Candia and Egypt, flowering from June to September.

The third rises with slender stalks near a foot high, either single or branching out at the bottom, and having a few very fine-cut leaves, somewhat like those of Dill. Each branch is terminated by one star-pointed flower, of a pale blue colour, without any leafy involucre: they are succeeded by capsules, having five short horns, inclining different ways at the top, and are filled with rough black seeds. It is a native of Germany, &c. flowering from June to September.

There is a variety with white flowers, and another with double flowers.

The fourth species rises near a foot and half high; the lower leaves are finely cut; but those on the stalks are cut into broader segments: the flowers are larger than those of the other species, and of a fine blue colour, with green veins at the back: the nectaries of a sea-green colour: the pistils are of equal length with the petals; they with the stamens are of a deep purple or puce colour: the capsule has five horns, and is of a firmer texture than any of the other. It grows naturally in Spain and the South of France, flowering from June to September.

There is a variety with double flowers.

The fifth rises with a branching stalk a foot and a half high; with pretty long leaves, finely divided: the flowers are produced at the end of the branches: the petals are yellowish; at the base of these are placed eight nectaries, between

Narcissus Jonquilla
 2 Jonquill.

which arise a great number of stamens, with an unequal number of germs, from five to eight or nine, oblong and compressed: the capsules are joined together on their inner side, terminate in horns, open longitudinally, and contain many thin compressed seeds, having borders round them. It is a native of Syria, flowering from July to September.

Culture.—They are all increased by sowing the seeds on light earth where the plants are to remain, as they seldom succeed well when transplanted in patches at proper distances; and when the plants are come up, they should be thinned, leaving only three or four in each patch, keeping them afterwards clear from weeds.

The best season for sowing is March; but if some be sown in August, soon after they become ripe, on a dry soil and in a warm situation, they will abide the winter, and flower strong the succeeding year. By sowing the seeds at different times, they may be continued in beauty most part of the summer season.

As they are all annual plants, they require to be raised every year.

The varieties with double flowers are chiefly introduced into flower gardens.

They afford ornament and variety among other annuals in the clumps and borders.

NIGHTSHADE. See **SOLANUM**.

NOLANA, a genus containing a plant of the herbaceous trailing annual kind.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Asperifoliae*, or *Luridae*.

The characters are: that the calyx is a one-leaved perianthium, turbinate at the base, five-parted, five-cornered: segments cordate, acute, permanent: the corolla is one-petalled, bell-shaped, plaited, spreading, somewhat five-lobed, twice as large as the calyx: the stamina have five awl-shaped filaments, erect, equal, shorter than the corolla: anthers sagittate: the pistillum is as five roundish germs: style among the germs, cylindric, straight, the length of the stamens: stigma capitate: the pericarpium properly none: (drupes five, decumbent, three- or five-celled:) the seeds five, with a succulent rind, roundish, with the inner base naked, immersed in the receptacle, two-celled and four-celled (solitary).

The species is *N. prostrata*, Trailing Nolana.

It has an annual root, simple, filiform, often three feet long, blackish: the stem a foot long, herbaceous, prostrate, roundish, very smooth, with white dots scattered over it: the branches alternate, the lower ones the length of the stalk:

the leaves alternate, two together, reflex, rhomb-ovate, quite entire, blunt, somewhat fleshy, an inch long, somewhat papulose, even, flat, veined, unequal, alternately larger and smaller. According to Miller they come out single at some joints, by pairs at others, and frequently three or four at the upper joints: the petioles ancipital, scarcely shorter than the leaves, smooth, those belonging to the upper leaves vaguely ciliate: the peduncles lateral, solitary, spreading a little, an inch long, one-flowered, round, thicker at top, hairy: the flowers inferior. It is a native of Java.

Culture.—These plants may be raised by sowing the seeds on a hot-bed in March. When the plants are fit to remove, they should be planted out singly into small pots filled with light earth, plunging them into a fresh hot-bed to bring them forward. When their flowers open in the summer, as July, they should have a large share of air admitted when the weather is warm, to prevent their falling away without producing seeds. Under this management the plants often continue flowering till the early frosts destroy them, and ripe seeds are produced in the beginning of the autumn.

They afford variety among other tender annuals.

NOLI ME TANGERE. See **IMPATIENS**.

NONE-SO-PRETTY. See **SAXIFRAGA**.

NOSE-BLEED. See **ACHILLEAS**.

NUCIPERSICA. See **AMYGDALUS**.

NURSERY, a portion of ground set apart for the raising and nursing various sorts of trees, shrubs, and herbaceous plants to proper states of growth for supplying the different gardens, orchards, plantations, and other departments.

In these situations are raised all the different sorts of fruit-trees, and fruit-bearing shrubs, by nursing and training them up to proper sizes and growths for planting where they are to remain to produce their fruit, as well as the vast train of forest-trees, hardy ornamental trees, and deciduous and ever-green shrubs, training them up properly for the purposes for which they are designed in plantations and pleasure-grounds.

And various sorts of hardy herbaceous plants, both of the fibrous-, bulbous-, and tuberous-rooted kinds may be here provided in proper states for being planted out.

These different sorts of plants are raised by seed, suckers, layers, cuttings, slips, off-sets, parting the roots, grafting, budding, &c. as directed under their several heads.

And as some of the various sorts are drawn off annually, to supply different situations, a fresh supply of young plants should be accord-

ingly raised every year in the Nursery, of most of the various kinds, so as to have it always fully stocked with most kinds in different states of growth; some in seed-beds, others transplanted in nursery-rows; some one year, others two, three, or several years: all of which should be well attended to, that there may be a sufficiency of plants of all sorts for furnishing every different department of gardening as they may be wanted.

In public Nursery-grounds, it is customary to have convenient green-houses, glass-cases, and stoves, with their proper appendages, for raising tender exotics from the warmer parts of the globe, which are always placed in the warmest and most sunny situations, having their fronts directly facing the south, to have all possible benefit from the sun's influence; which serve for raising and nursing the various tender plants to a proper growth for furnishing other larger conservatories, green-houses, &c.

Size, Soil, and Situation. In respect to the extent or dimensions of Nursery-grounds, they should be according to the quantity of plants required, or the demand for sale: if for private use, from a quarter or half an acre to five or six may be proper, which should be regulated according to the extent of the garden-ground and plantations they are required to supply; and if for public or general cultivation, not less than three or four acres of land will be worth occupying, and from that to fifteen or twenty acres, or more, may be requisite, in proportion to the demand.

The soil for Nursery-grounds should be of different qualities, in order that it may suit different sorts of trees and plants.

Nursery-men generally prefer a loamy soil of a moderately light nature: however, they may be formed of any good moderately light land, that has fifteen or eighteen inches depth of good working soil, but if two or three spades deep it will be the better; and where there is scope of ground to choose from, that where there is a good depth, and a naturally rich or good soil, should be preferred, as the soil of a Nursery cannot be too good, notwithstanding what has been advanced to the contrary; as where the soil is poor and lean, the plants are mostly languid, weak, and stunted, no art being able to improve them; while those raised in a good mellow soil always assume a free growth, and advance with strength and vigour. It is not requisite, however, that the soil should be very rich, nor over manured: a medium between the two extremes is the most proper, such as good mellow pasture land, having the sward trenched to the bottom, which is ex-

cellent for the growth of trees; and any similar eligible soil of corn-fields is also extremely proper: any other good soil of the nature of common garden-earth is likewise well adapted for a Nursery-ground.

As to situation; where it is rather low than high it is better, as being naturally warmer, and more out of the power of cutting and boisterous winds than a higher situation, though where some parts of the ground are high and others low, it may be an advantage, in better suiting the nature of the different plants. It is also of vast advantage to have Nursery-grounds fully exposed to the sun and free air, and, if possible, where there is the convenience of having water for the occasional watering of young seedlings, and newly removed plants.

When for private use, where there is room, Nursery-grounds may either be entirely detached, or contiguous to the outer boundaries of the shrubbery plantations of the pleasure-ground, and so contrived as to lead insensibly into it by winding walks, so as to appear part of the garden or shrubbery.

Method of inclosing, preparing, and laying out. In respect to the outside fence, it may either be a hedge and ditch, or a paling; the former is the cheapest, and most durable; though where hares and rabbits abound paling fences are most eligible.

Paling, or other similar close fence, is however in general, for some part, extremely useful to train young wall-trees to a proper growth for garden-walls, &c.

After thus fenced in, the ground should be all regularly trenched over one or two spades deep, according to the natural depth of the soil; after which, proceed to divide it by walks into quarters, and other parts; letting a principal walk lead directly through the middle or some principal part, which may be from five to eight or ten feet wide, according to circumstances, having a broad border on each side: another walk should be carried all round next the outward boundary, four or five feet wide, leaving an eight or ten feet border next the fence all the way; dividing the internal part by smaller cross walks, so as to form the whole into four, six, or eight principal divisions.

One or more of these divisions should be appropriated for the reception of all sorts of seeds, for raising plants to furnish the other parts; subdividing it into four feet wide beds, with foot-wide alleys at least between bed and bed. In these beds should be sown seeds, &c. of all such trees, shrubs, and herbaceous plants as are raised from seed; and which should

contain the various sorts of kernels and stones of fruit, to raise stocks for grafting and budding upon, as well as the seeds of forest-trees, ornamental trees, shrubs, &c. and of numerous herbaceous perennials, of the fibrous and bulbous-rooted tribes.

The season for sowing is both spring and autumn, according to the nature of the different sorts, as may be seen under their different heads. When the young tree and shrub seedling-plants thus raised are one or two years old, they should be planted out in Nursery-rows into the other principal divisions, but many kinds of herbaceous plants require to be picked out from the seed-beds when only from two to three or four months old. And, on the contrary, most kinds of bulbous seedlings will not be fit for planting out in less than one or two years at the shortest periods.

Another part of these grounds should be allotted for stools of various trees and shrubs, for propagation by layers, by which vast numbers of plants of different kinds may be raised. These should be strong plants set in rows three or four feet distance every way: such of them as naturally rise with tall stems, after being planted one year, are headed down near the ground, to force out many lower shoots conveniently situated for laying them down. See **STOOLS** and **LAYING**.

The cuttings, suckers, slips, off-sets, &c. of hardy trees, shrubs, and plants, may be planted out in any convenient part of the ground in shady borders, &c.; but for the more tender kinds, some warm sheltered situation should be provided.

The other principal divisions of these grounds should be left for the reception of various sorts of seedling plants from seminary quarters; as well as for those that are raised from suckers, layers, cuttings, &c. to be planted in rows from one to two or three feet asunder, according to their natures and growths, allowing the tree and shrub kinds treble the distance of the herbaceous perennial sorts. Of the tree and shrub kinds some are to be planted for stocks to graft and bud the select sorts of fruit-trees and other choice plants upon, that are usually propagated by such methods; others should be trained up entirely on their own roots without budding and grafting, as in most forest and other hardy tree kinds; as well as almost all the sorts of shrubs.

It is also proper to have some dry warm sheltered situation in the full sun in these grounds, for occasional hot-beds of dung or tan, for raising and forwarding many sorts of tender or curi-

ous exotics by seed, cuttings, suckers, slips, &c. which should be furnished with suitable frames and lights, hand-glasses, garden-mats, and other requisites for that sort of culture.

Methods and Times of Stocking with Plants. The particular modes of cultivation are fully explained under the different heads of the plants, and the operations that are necessary in raising them to the best advantage.

As to the seasons for performing the works of sowing, planting, &c. they are different in different kinds, but the autumn and spring are the principal seasons: for planting out or removing, the principal season is about October and in April, for tender kinds, especially the evergreen tribe; but most other hardy trees and shrubs may be transplanted any time in winter, in open mild weather. The nature of the soil should, however, be regarded in this business.

The hardy herbaceous fibrous-rooted plants may be removed almost any time, either in autumn or spring, and many sorts even in the summer. But for the older or larger plants, the autumn or very early spring are the best periods, which are the only proper seasons for dividing or slipping the roots of all these kinds for further increase.

And for the bulbous and such tuberous roots whose leaves, like most of the bulbous tribe, decay in the summer, the proper season for planting or removing them is the spring and summer months, when their flower-stalks decay, as well as to separate their off-sets for increase; which may either be planted again directly, or kept out of ground one, two, or several months, though it is proper to plant the principal part again in autumn, unless where retained for sale, &c.

The succulent perennial sorts may be removed almost any time in the spring, summer, or early autumn, but the last is the best. But most kinds of succulent cuttings succeed best when planted in the summer season.

Methods of disposing the Plants.—In the distribution of the different sorts in these grounds, each should be separate: the fruit-forest-trees, &c. occupying spaces by themselves nearly together; all the shrub kind should also be ranged in separate places, allotting suitable spots for herbaceous perennials and tender plants, defended with yew or privet hedges, or a reed fence, &c. in which may be set such plants, in pots, as are a little tender whilst young, and require occasional shelter from frost, but not so tender as to require to be housed as green-house plants, &c. And in such places, frames of various sizes may be placed, either to be covered occasionally with glass lights, or

with mats, to contain some of these more choice tender kinds in pots, to be nursed a year or two, or longer, with occasional shelter, till gradually hardened to bear the open air.

The arrangement of all the sorts in the open grounds should always be in lines or nursery-rows, as already suggested; placing the fruit-tree stocks, &c. for grafting and budding upon, in rows two feet asunder, when for dwarfs; but for standards two feet and a half, and a foot and a half in the lines. But as after being grafted and budded they become fruit-trees, &c. where they are to stand to grow to any large size, they should be allowed the width of a yard between the rows. Forest-trees should also be placed in rows from two to three feet asunder, and half that distance in the rows; varying the distance both ways, according to the time they are to stand: the shrub kind should likewise be arranged in rows about two feet asunder, and fifteen or eighteen inches distant in each line; and as to the herbaceous plants, they may generally be disposed in four-feet-wide beds, or large borders, in rows, or distances, from six to twelve or eighteen inches asunder, according to their nature of growth, and time they are to stand or remain in them.

By this mode of arrangement, a great number of plants are included within a narrow compass, but which is sufficient, as they are only to remain a short time; and besides, they are more readily kept under proper regulation.

In public grounds of this sort, many kinds of seedling-trees and shrubs are planted out often in much closer rows at first than these, not only in order to husband the ground to the best advantage, but by standing closer it encourages the stem to shoot more directly upward, and prevent their expanding themselves much any where but at top; as for instance, many sorts of ever-greens that are of slow growth the first year or two, such as the pine-trees, firs, and several others; which the nursery-gardeners often prick out from the seminary, first into four feet-wide beds, in rows lengthways, six inches asunder; and after having one or two years growth here, transplant them in rows a foot asunder; and in a year or two after, give them another and final transplantation in the Nursery, in rows two or three feet asunder, as above: these different transplantings encourage the roots to branch out into many horizontal fibres, and prepare them better for being finally planted out.

The various sorts of Nursery-plants, after being raised in some of the above methods, are sometimes pricked out by dibble, in other

cases put in by the spade, either by trenches, slitting-in, trenching, or holing; and some are drilled in by a spade or hoe, according to the kinds.

Sometimes young seedling-trees and shrubs are pricked out from the seminary by dibble; sometimes put in by the spade in the following methods: first, having set a line to plant by, the spade is stricken into the ground with its back close to the line, and another stroke given at right angles with it; then a plant set into the crevice made at the second stroke, bringing it close up into the first-made crevice even with the line, pressing the mould close to it with the foot; then proceeding to plant another in the same way, and so on.—A second method, for plants with rather larger roots, is to strike the spade down with its back close to the line, and then cut out a narrow trench with it close along the line, making the side next the line perfectly upright, placing the plants upright against the back of the trench close to the line, at the proper distances; and as the work proceeds, trimming in the earth upon their roots: when one row is thus planted, the earth should be trodden gently all along close to the plants; and then proceed to plant another row in the same manner. Another method of planting out small tree and shrub plants is, after having set the line as above, to turn the spade edgewise to the line, casting out the earth of that spit, then a person ready with plants, setting one in the cavity close to the line, and directly taking another such spit, turning the earth in upon the roots of the plant, and then placing another plant into the second cut, covering its roots with the earth of a third spit, and so on to the end: but sometimes, when the roots are much larger, holes are made along by the line wide enough to receive the roots freely every way, covering them in as above, as the work proceeds, always pressing the earth gently with the foot close to the roots, and closing it about the stems, to settle the plants firmly in their proper positions.

Fibrous-rooted herbaceous plants are mostly planted with a dibble, except when the roots are large and spreading, or such as are removed with balls of earth; when they are more commonly planted by holing them in with a garden trowel, or small spade for the purpose.

But bulbous and tuberous-rooted plants, such as lilies, tulips, anemones, ranunculuses, &c. are commonly planted with a dibble, and many sorts may be planted in drills drawn with a hoe.

They are also sometimes planted, by raking or trimming the earth from off the top of the beds

from about three to four or five inches deep, into the alleys, then placing the roots in rows upon the surface, thrusting the bottoms a little into the ground, and immediately covering them with the earth which was drawn off into the alleys, spreading it evenly over every part, so as to bury all the roots to an equal depth in the soil.

The tender kinds of exotic plants, that require occasional shelter whilst young, should many of them be potted, in order for moving to warm situations in winter; or some into frames, &c. to have occasional shelter from frost, by glasses or mats, as they may require; hardening them, however, by degrees to bear the open air fully in the Nursery the year round. And the most tender kinds, that require the aid of a greenhouse or stove, should all be potted, and placed in their proper situations. See GREEN-HOUSE and STOVE PLANTS.

General Culture of the Plants.—In the management of the various hardy Nursery-plants, those intended as stocks or fruit-trees, should have their stems generally cleared from lateral shoots, so as to form clean straight stems, but never to shorten the leading shoot, unless it is decayed, or becomes very crooked, in which case it may be sometimes proper to cut it down low in spring, to shoot out again, training the main shoot for a stem, with its top entire, till grafted or budded. See GRAFTING, BUDDING, and TRAINING.

But in the culture of the fruit-tree kind, the sorts designed for principal wall-trees, particularly such as peaches, nectarines, apricots, &c. should, when of one year's growth from grafting and budding, be planted against some close fence, as a wall, paling, reed-hedge, &c. and their first graft or bud-shoot headed down in the spring, to promote an emission of lower lateral shoots and branches, in order to be regularly trained to the fence in a spreading manner for two or three years, or till wanted, to form the head in a regular spreading growth, which in public grounds of this kind should always be ready in proper training, to supply those who may wish to have their walls covered at once by such ready trained trees. And a similar training, both for wall and espalier fruit-trees, may be practised with some principal sorts in the Nursery-rows in the open quarters of the ground, by directing their branches, in a spreading manner, to stakes placed for the purpose.

Standard fruit-trees should only be trained with a clean single stem, five or six feet for full standards, by cutting off all lateral shoots arising below: half-standards should be trained

Vol. II.

with three- or four-foot stems, and dwarf standards in proportion by the same means.

The heads of the standards in some may be directed by having the first immediate shoots from the graft or bud, when a year old, pruned short in spring, to procure lateral shoots, in order to form a fuller spread of branches, proceeding regularly together from near the summit of the stems, and thus give a more regular branchy growth to them.

Forest-trees should, in general, be encouraged to form straight clean single stems, by occasional trimming off the largest lateral branches, which also promotes the leading top-shoots in rising straight, and faster in height; always suffering that part of each tree to shoot at full length; that is not to top it, unless where the stem divides into forks, when the weakest should be trimmed off, and the straightest and strongest shoots or branches left to shoot out at their proper length to form the aspiring tops.

The different sorts of shrubs should mostly be suffered to branch out in their own natural way, except merely regulating very disorderly growths; and some sorts may be trained with single clean stems, from about one foot to two or three high, according as may be thought proper. But shrubs in general appear the most agreeable when permitted to shoot out laterally all the way, so as to be branchy or feathered to the bottoms of the stems.

The fruit-trees in each species should, as soon as grafted or budded, have all the different varieties numbered, by placing large flat-sided sticks at the ends of the rows, for which purpose the spokes of old coach-wheels, or any thing about that size of any durable wood, answers very well, painting or marking upon them the numbers, and entering them in the Nursery-book, with the name of the varieties to which the number-sticks are placed; by which, at all times, a ready recourse may be had to the sorts wanted.

And it is useful to employ the same means to trees, shrubs, and herbaceous plants, especially the varieties of particular species, when they are numerous, such as in many of the flowery tribes; as auriculas, carnations, tulips, anemones, ranunculuses, &c.

Watering Nursery-plants is very requisite in dry hot weather, in spring and summer; such as seed-beds and tender seedling-plants, while young, and when first planted out, till they have taken good root; also, occasionally, to new-laid layers and newly-planted cuttings in dry warm weather; but as to hardy trees and shrubs of all sorts, when planted out at the proper time, as not too late in the spring, no great regard need be paid

X

in this respect, as they generally succeed very well without.

The next business is, in every winter or spring, to dig the ground between the rows of all sorts of transplanted plants in the open Nursery-quarters, a practice which is particularly necessary to all the tree and shrub kinds that stand wide enough in rows to admit the spade between them; this work is by the Nursery-men called *turning-in*; the most general season for which is any time from October or November until March; but the sooner it is done the more advantageous it will be to the plants. The ground is to be dug only one spade deep in these cases, proceeding row by row, turning the top of each spit clean to the bottom, that all weeds on the top may be buried a proper depth. It is a most necessary annual operation, both to destroy weeds, and to increase the growth of the young plants.

And in the summer season great attention is necessary to keep all sorts clean from weeds; the seedlings growing close in the beds must be hand-weeded; but among plants of all sorts that grow in rows wide enough to admit the hoe, it will prove not only most expeditious, but, by loosening the top of the soil, promote the growth of all kinds of plants. It should always be performed in dry weather, and before the weeds grow large. See HOB and HOBBING.

As soon as any quarter or part of these grounds are cleared from plants, others must be introduced in their room from the seminary; the ground being previously trenched over for the purpose, giving it the addition of manure if necessary.

It is supposed by some to be of advantage to plant the ground with plants of a different kind from those which occupied it before; but this is probably not very material.

The tender or exotic plants of all kinds that require shelter only from frost whilst young, and by degrees become hardy enough to live in the open air, should, such of them as are seedlings in the open ground, have the beds arched over with hoops, or rods, at the approach of winter, in order to be sheltered with mats in severe weather; and those which are in pots, either seedlings or transplanted plants, should be removed in October in their pots to warm sunny situations sheltered with hedges, &c. placing some close under the fences facing the sun, where they may have occasional covering of mats in frosty weather; others that are more tender being placed in frames, to have the occasional covering either of glass-lights or mats, &c. observing that they are gradually to be hardened to the

open ground, and need only be covered in frosty weather; at all other times they should remain fully exposed, and, by degrees, as they acquire age and strength, become inured to bear the open air fully; so as when they arrive at from two or three to four or five years old, they may be turned out into the open ground.

The stove and green-house kinds must be managed according to the directions given under these heads. See GREEN-HOUSE PLANTS.

NUT-TREE. See CORVLUS.

NYCTANTHES, a genus containing plants of the shrubby exotic flowering kind.

It belongs to the class and order *Diandria Monogynia*, and ranks in the natural order of *Sepiariæ*.

The characters are: that the calyx is a one-leaved perianthium, tubular, truncate, quite entire, permanent: the corolla one-petalled, salver-shaped: the tube cylindric, the length of the calyx: border five-parted, spreading, with the lobes two-lobed: the stamina have two filaments in the middle of the tube, very short: anthers oblong, the length of the tube: the pistillum is a superior germ, subovate: style filiform, the length of the tube: stigmas two, acute: the pericarpium is an obovate capsule, compressed, with an emarginate dagger-point, coriaceous, two-celled, bipartile: cells parallel, appressed, valveless: the seeds are solitary, obovate, convex on one side, flat on the other, fastened to the bottom of the cell.

The species cultivated is: *N. arbor tristis*, Square-stalked Nyctanthes. Other species may be cultivated for variety.

It is a shrub, with four-cornered, rugged branches: the leaves are opposite, petioled, ovate, oblong, quite entire, longer than the branch-joints, rugged on both sides: the peduncles axillary, opposite, solitary, four-cornered, shorter by half than the leaf, two-leaved at top, with three-flowered pedicels: the partial involucre four-leaved: the leaflets are obovate, the length of the calyxes, blunt, containing three sessile florets: the corolla funnel-shaped, with a six- or eight-cleft border: the capsule coriaceous, superior, obcordate or obovate, turgidly lenticular, in the twin, middle ventricose and marked with a longitudinal elevated streak, compressed at the sides into a narrow sharp margin, the rest brittle, two-celled, bipartile; with the segments plano-convex, of a brown chestnut

colour on the outside, pale within, quite entire, valvaceous. It is a native of the East Indies.

Culture.—It may be increased by layers and cuttings. The layers may be laid down in the early part of the summer, in the usual method, being made from the young branches, plunging the pots containing them in a bark hot-bed.

The cuttings should be taken from the young shoots, be planted out at the same time, and managed in the same manner.

The plants, when fully rooted in either way, may be removed into separate pots. They should have due supplies of water, and be pruned and removed into larger pots as there may be occasion.

They are very ornamental and fragrant among other potted tender plants.

NYMPHÆA, a genus comprising plants of the herbaceous flowery aquatic kind.

It belongs to the class and order *Polyandria Monogynia*, and ranks in the natural order of *Succulentæ*.

The characters are: that the calyx is an inferior perianthium, four-, five-, or six-leaved, large, coloured above, permanent; the corolla has numerous petals (often fifteen) placed on the side of the germ, in more than one row: the stamina have numerous filaments (often seventy) flat, curved, blunt, short: anthers oblong, fastened to the margin of the filaments: the pistillum is an ovate germ, large: style none: stigma orbiculate, flat, peltate-sessile, rayed, crenate at the edge, permanent: the pericarpium is a hard berry, ovate, fleshy, rude, narrowed at the neck, crowned at the top, many-celled, (cells from ten to fifteen) full of pulp: the seeds very many, and roundish.

The species are: 1. *N. lutea*, Yellow Water Lily; 2. *N. alba*, White Water Lily; 3. *N. Lotus*, Egyptian Water Lily; 4. *N. nelumbo*, Peltated Water Lily.

The first has the leaves smooth, plane, except that they turn up a little at the edge to keep off the water, tough and pliant, ten or twelve inches in diameter, floating, ovate or nearly orbicular, bright green above, paler underneath, with branched raised nerves or veins: the petioles are smooth, three-sided, their length depending on the depth of water, sometimes five feet and a half in length. The case is the same with the peduncle, which always elevates the flower above the water; but after it is impregnated, the seeds are ripened under water, and fall into the mud at bottom to produce new plants: the peduncles are round, succulent, and one-flowered: the flowers an inch and half in diameter, having

a vinous smell. It is a native of most parts of Europe, flowering in July and August.

The second species has a tuberous root, frequently the size of the human arm, creeping far and wide and deep in mud: the whole plant is larger in all its parts than the first: the leaves are much the same, only larger: the petioles and peduncles round, within full of pores, four of which are generally larger than the rest; hairs interwoven between: the flowers large, being sometimes six inches in diameter, very handsome and double.

According to Linnæus, the flower raises itself out of the water and expands about seven o'clock in the morning, and closes again, reposing upon the surface, about four in the evening. It is a native of most parts of Europe, flowering in July and August.

The third resembles the second very much in the form of the flower and leaves, but the latter are toothed about the edge. It is a native of the hot parts of the East Indies, Africa, and America, flowering about the middle of September near Cairo, in Lower Egypt. The Arabians call it Nuphar. A bread was formerly made of the seed when dried and ground.

The fourth species has a horizontal root, long, creeping, consisting of joints linked together, ovate-oblong, white, fleshy, esculent, tubular within: the leaves exactly peltate, with a cavity in the centre above, and dichotomous veins springing from the same centre, orbiculate, with a point on each side, a little waved, thin, paler underneath, smooth, of different sizes, from four to twelve inches: the petioles erect, very straight, round, hispid or muricated, thicker below, attenuated above: the peduncle the thickness of a finger below, attenuated above, spongy, muricated, one-flowered: the flowers as large as the palm of the hand, or larger, purple. It is a native of the Indies, &c.

The Chinese have the roots not only served up in summer with ice, but laid up in salt and vinegar for winter: the seeds are somewhat of the size and form of an acorn, and of a taste more delicate than that of almonds: the ponds in China are generally covered with it, and exhibit a very beautiful appearance when it is in flower; and the flowers are no less fragrant than handsome.

Culture.—The two first sorts may be best increased by procuring some of their seed-vessels just as they become ripe and ready to open, and throwing them into canals, ponds, ditches, or other standing waters, where the seeds, sinking to the bottoms, afford plants in the following spring floating upon the surface of their waters.

When they have been once fixed to the place in this way, they multiply greatly, so as to cover such places in a short time.

They are also capable of being cultivated in large troughs or cisterns of water, having earth at the bottoms, flourishing very well, and producing annually large quantities of flowers.

The third and fourth species, as being tender, should be kept in such troughs or cisterns, and be set in a corner of the stove. In their native situations they are increased both by their roots and seeds as the common sorts in this climate.

NYSSA, a genus containing a plant of the aquatic ornamental tree kind.

It belongs to the class and order *Polygamia Dioecia*, and ranks in the natural order of *Umbellales*.

The characters are: that in the male the calyx is a five-parted perianthium, spreading, with a plane bottom: there is no corolla: the stamina have ten awl-shaped filaments, shorter than the calyx: anthers twin, the length of the filaments: hermaphrodite—the calyx is a perianthium as in the male, sitting on the germ: there is no corolla: the stamina have five awl-shaped filaments, erect: anthers simple: pistillum is an ovate germ, inferior: style awl shaped, curved inwards, longer than the stamens: stigma acute: the pericarpium is a drupe: the seed is an oval nut, acute, scored with longitudinal grooves, angular, irregular.

The species are: 1. *N. integrifolia*, Mountain Tupelo; 2. *N. denticulata*, Water Tupelo.

The first rises with a strong upright trunk to the height of thirty or forty feet, and sometimes near two feet in diameter; sending off many horizontal, and often depending branches: the leaves are obovate, a little pointed, entire, of a dark green and shining upper surface, but lighter and a little hairy underneath: those of the male trees are often narrower and sometimes lance-shaped. The flowers are produced upon pretty long common footstalks, arising from the base of the young shoots, and dividing irregularly into several parts, generally from six to ten, each supporting a small flower, having a calyx of six or seven unequal leaves, and from six to eight awl-shaped spreading stamens, supporting short four-lobed anthers: the female trees have fewer flowers produced upon much longer simple cylindrical footstalks, thickened at the extremity, and supporting generally three flowers, sitting close, and having a small involucre. They are composed of five small oval leaves, and in the centre an awl-shaped incurved style, arising from the oblong germ, which is inferior, and becomes an oval oblong berry, of

a dark purplish colour when ripe: the timber is close-grained, and curled so as not to be split or parted; and therefore much used for wheels, &c. It grows naturally in Pennsylvania, and perhaps elsewhere.

The second species rises with a strong upright trunk to the height of eighty or a hundred feet in its native situation, dividing into many branches towards the top: the leaves are pretty large, of an oval-spear-shaped form, generally entire, but sometimes somewhat toothed, and covered underneath with a whitish down: they are joined to long slender footstalks, and affixed to the branches in somewhat of a verticillate order, presenting a beautiful varied foliage: the berries are near the size and shape of small olives, and are preserved as that fruit is by the French inhabitants upon the Mississippi, where it greatly abounds, and is called the Olive-tree: the timber is white, and soft when unseasoned, but light and compact when dry, which renders it very proper for making trays, bowls, &c. It grows naturally in wet swamps, or near large rivers, in Carolina and Florida.

Culture.—These trees may be increased by sowing the seeds procured from the places where they grow naturally, putting them into the ground as soon as they are procured, as they lie long before they vegetate.

They should be sown in pots filled with light loamy earth, placing them where they may have only the morning sun; and during the first summer the pots should be kept clean from weeds, being well watered in dry weather. The pots should be plunged into the ground in the following autumn; and, if the winter prove severe, cover them with old tan, peas-haulm, or other similar light covering. And in the following spring they should be plunged into a moderate hot-bed, hooped and covered over with mats; keeping the earth constantly moist.

By this means the plants are brought up in the spring, when they should be gradually hardened to bear the open air; and during the following summer, the pots again plunged into an eastern border, watering them in dry weather, carefully removing them into a frame in the autumn, where they may be screened from frost; but in mild weather be exposed to the open air. In the spring following, before they begin to shoot, they should be parted carefully, planting each in a small pot filled with loamy mould; and when they are plunged into a moderate hot-bed, it will promote their putting out new roots; after which they may be plunged in an eastern border, and be sheltered again in winter under a frame. In the third spring, such plants as have made

the greatest progress may be planted out in a loamy soil, in a sheltered situation, where they may be capable of enduring the cold of this climate. They make the greatest progress where the soil is inclined to be moist.

They may likewise be propagated by layers

and cuttings, planted out in the autumn or spring in the usual manner.

The plants afford ornament and variety in shrubbery and other parts, where the ground is of a moist quality.

O C I

OAK. See **QUERCUS**.
OAK JERUSALEM. See **CHENOPODIUM**.
OCIMUM, a genus containing plants of the tender herbaceous aromatic annual kind.

It belongs to the class and order *Didynamia Gymnospermia*, and ranks in the natural order of *Verticillatæ*.

The characters are: that the calyx is a one-leaved perianthium, two-lipped, very short, permanent: upper-lip flat, orbiculate, wider, ascending: lower-lip four-cleft, acute, converging: the corolla is one-petalled, ringent, resupine: tube very short, spreading; one lip turned upwards, wider, half-four-cleft, blunt, equal; the other lip turned downwards, narrower, entire, serrate, longer: the stamina have four filaments, declined; two a little longer, and two putting forth a reflex process at the base: anthers half-mooned: the pistillum is a four-parted germ: the style filiform, situation and length of the stamens: stigma bifid: there is no pericarpium: calyx closed, cherishing the seeds: the seeds four, ovate.

The species cultivated are: 1. *O. Basilicum*, Common Sweet Basil; 2. *O. minimum*, Bush Basil; 3. *O. tenuiflorum*, Slender-spiked Basil.

The first has the stem suffruticose, three feet high (a foot and half), erect, round, tomentose; with straight, ascending branches: the leaves somewhat acute, serrate, pubescent, brownish-red, waved, petioled, smelling like cloves: the flowers are white, small, in long, upright, terminating spiked racemes. The whole plant has a strong scent of cloves. It is a native of the East Indies, flowering in July and August.

There are varieties with purple fringe-leaves; with green fringe-leaves; green with studded leaves; and the Large-leaved Basil.

The middle-sized variety, or that which is used in the kitchen, especially in French cookery, rises about ten inches high, sending out opposite, four-cornered branches from the very bottom:

O C I

the leaves are ovate-lanceolate, ending in acute points, indented on their edges. The whole plant is hairy, and has a strong scent of cloves, which to some is very agreeable.

The chief sub-varieties of which are: the Common Basil, with very dark green leaves and violet-coloured flowers; the Curled-leaved Basil, with short spikes of flowers; the Narrow-leaved Basil, smelling like fennel; the Middle Basil, with a scent of citron; the Basil with studded leaves; and Basil with leaves of three colours.

The second species is a low bushy plant, seldom more than six inches high, branching from the bottom, and forming an orbicular head: the leaves small, smooth, on short footstalks: the flowers in whorls towards the top of the branches, smaller than those of the first sort, and seldom succeeded by ripe seeds in this climate. It is a native of the East Indies, annually flowering in July and August.

There are varieties with black purple leaves, and with variable leaves.

The third has the stem from one to two feet high, roundish, purple, brachiate, having spreading hairs scattered over it: the branches shorter: the leaves bluntly serrate, soft, on long petioles: the spikes terminating, in threes, long, narrow, peduncled; with opposite, smooth, bractes, closely reflex: the flowers three from each bracte, subsessile, which are so small as scarcely to be visible to the naked eye: they begin to open from the top of the spike. It is a native of Malabar, &c.

Culture.—They are all capable of being increased by sowing the fresh seeds in the latter end of March, upon a moderate hot-bed, covered to the depth of five or six inches with good light mould, putting them in a quarter of an inch deep, fresh air being given daily, and slight waterings occasionally. When the plants have attained a few inches in growth they should be pricked out upon another hot-bed four inches apart, or set in pots

of a small size, plunging them in the hot-bed, water and occasional shade being given till fresh rooted, with fresh air and water in small proportions afterwards. In the latter end of the spring or beginning of summer, they should be begun to be hardened, and in the hot weather set out in the open air where wanted. Some may be set out in the borders in the open ground, a slight watering being given at the time.

In order to obtain good seeds, a few of the potted plants should be placed in a good greenhouse or glass case in the latter end of the summer, fresh air being freely admitted.

The first sort and varieties are often used as culinary herbs, and all the sorts may be set out among other potted plants in rooms and windows, especially the bush sort, as well as in the borders and clumps for ornament and variety.

OENOTHERA, a genus containing plants of the herbaceous, biennial, perennial and under shrubby perennial kinds.

It belongs to the class and order *Octandria*, *Monogynia*, and ranks in the natural order of *Calycanthemæ*.

The characters are: that the calyx is a one-leaved, superior, deciduous perianthium: tube cylindrical, erect, long, deciduous: border four-cleft: the segments oblong, acute, bent down: the corolla has four petals, obcordate, flat, inserted into the interstices of the calyx, and the same length with the divisions of the calyx: the stamina have eight awl-shaped filaments, curved inwards, inserted into the throat of the calyx, shorter than the corolla: anthers oblong, incumbent: the pistillum is a cylindrical germ, inferior: style filiform, the length of the stamens: stigma four-cleft, thick, blunt, reflex: the pericarpium is a cylindrical capsule, four-cornered, four-celled, four-valved, with contrary partitions: the seeds very many, angular, naked: the receptacle columnar, free, four-cornered, with the angles contiguous to the margin of the partitions.

The species cultivated are: 1. *O. biennis*, Broad-leaved Tree-Primrose; 2. *O. longiflora*, Long-flowered Tree-Primrose; 3. *O. mollissima*, Soft Tree-Primrose; 4. *O. fruticosa*, Shrubby Tree-Primrose; 5. *O. pumila*, Dwarf Tree-Primrose.

The first has a biennial fusiform fibrous root, yellowish on the outside, white within: from this, the first year, arise many obtuse leaves, which spread flat on the ground; and from among which, the second year, the stems come out, three or four feet high, upright, of a pale green colour, the thickness of a finger, not hollow but pithy, angular, slightly pubescent and rugged, tinged with purple, especially towards the bottom, branched alternately almost from the ground:

the root-leaves run down into a three-sided petiole an inch in length: the stem-leaves sessile, bright lightish green, pubescent on both sides, waved a little about the edge, and having a few small teeth near the base: they are from five to seven inches in length and two inches in breadth, having a considerable midrib running the whole length, very wide and tinged with purple towards the base, at the back very prominent, with white nerves springing from it, and curved towards the point: the flowers are produced all along the stalks on axillary branches, and in a terminating spike: the leaves on the former are similar to the stem-leaves, but much smaller, being not more than two inches long, and little more than half an inch in breadth: the flowers are solitary, each being separated by a leaflet or bracte, wider in proportion at the base than the proper leaves, and drawn more to a point, diminishing gradually towards the top of the spike, till they become linear, scarcely half an inch in length, and a line in breadth.

It is observed that the flowers usually open between six and seven o'clock in the evening, whence the plant is called Evening or Night-Primrose: the uppermost flowers come out first in June, the stalk keeping continually advancing in height, and there is a constant succession of flowers till late in autumn. It is a native of North America. The roots are said to be eaten in some countries in the spring season.

The second species has also a biennial root: the root-leaves are numerous, broad-lanceolate, toothletted, pubescent, with a white rib, obliquely nerved: the stems usually five, springing out below the root-leaves, quite simple, ascending, rough-haired, green with long spreading white hairs: the central stem grows up later: the stem-leaves are ovate-oblong, sessile, like the root-leaves: the flowers axillary from the upper leaves, with the germ and calyx hairy. It is remarked by Curtis, that luxuriant specimens exceed five feet in height, that the flowers are uncommonly large and showy, and continue blowing from July to October. It is a native of Buenos Ayres.

The third has a shrubby stalk more than two feet high, hairy, with narrow-lanceolate sessile leaves, a little waved on their edges, and ending in acute points: the flowers are axillary like the other sorts, at first pale yellow, but as they decay changing to an orange colour, smaller than those of the first sort: the seed-vessels slender, taper, hairy. It is also a biennial plant, and a native of Buenos Ayres, flowering from June to October.

The fourth species is a perennial, but altogether herbaceous, at least here, and therefore

 2 Dittany of Crete

improperly named *fruticosa*: the flowers which are large and showy, though they open in the evening, remain expanded during most of the ensuing day: the flower-buds, germ, and stalk, are enlivened by a richness of colour which contributes to render this species one of the most ornamental and desirable. It is a native of Virginia.

The fifth has also a perennial fibrous root: the lower leaves ovate, small, close to the ground: the stalk slender, near a foot high: the leaves smaller, light green, sessile, ending in blunt points: the flowers small, bright yellow: it sends up many flowering-stems, producing blossoms from April to July, opening in the morning as well as evening. It is a native of North America.

Culture.—These plants are all capable of being raised from seeds, and some of them by parting the roots and cuttings.

The seed should be sown either in the autumn or early spring, in the first and third sorts, upon a bed or border in the open ground, thinning and watering the plants properly, and keeping them free from weeds till the following autumn, when they may be removed with balls of earth about their roots to the places where they are to remain. Or some may be set out at the time of thinning in nursery-rows, six inches apart.

They also rise without trouble from the scattering of the seeds.

In the second sort, the seed should be put into the ground in the open borders or other parts, about the latter end of March, where the plants are to remain. One plant is sufficient in a place, which should have a stick set to support its branches when they have advanced a little.

The fourth sort may be readily increased by sowing the seeds as above, and by parting the roots and cuttings of the young branches, planting them out in the open borders or other places where they are to grow in the autumn, for the first method, and the spring for the latter, giving water as there may be occasion.

In the fifth sort, the seeds should be sown in pots of light earth in the autumn, plunging them in a hot-bed frame during the winter. When the plants have attained proper growth in the spring, they should be removed into separate pots, which should be protected in the following winter under a garden frame. And some may be planted out in the open ground, where they often succeed in mild winters.

The parted roots should be planted out in the spring, either in pots or the open ground.

The plants raised from seed are in general the best, as flowering more strongly.

By cutting down the stems of the plants in the first year of their flowering before they perfect their seeds, the plants may sometimes be rendered more durable.

The first two sorts, as has been seen, are biennial, and the others perennial; the former should of course be raised annually.

They are all proper for affording ornament and variety, either in the open ground or among other potted plants. The second and third sorts are often considered as green-house plants, but they succeed well in the open ground.

OFF-SET, a sort of sucker or small young plant, issuing from the sides of the main root of different sorts of perennial plants, whether bulbous-, tuberous-, or fibrous-rooted, by means of which they are often readily increased.

The method of increasing by Off-sets is applicable in general for all sorts of bulbous- and tuberous-rooted perennial plants, such as tulips, anemones, &c. in which there are small bulbs, or tubers, that on being planted out afford plants of exactly the same kind as those from which they are taken, and which, after having one or two years' growth, flower, produce seed, and furnish a supply of Off-sets in their turn.

In the vast tribe of fibrous-rooted perennial plants, most sorts afford a progeny of this sort, for propagating and perpetuating their respective species and varieties, both in the flowery kind, &c., and in some esculents, but more considerably in the former; by which numerous sorts of the most beautiful flowering perennials are multiplied.

Off-sets are therefore not only an expeditious and certain method of propagation, but by which there is a certainty of having the desired sorts continued, whether species or particular varieties.

They have this advantage over seedlings, that the plants of the flowery kind often flower in one year; whereas seedling plants of the bulbous kinds are frequently four, five, and sometimes six or seven years before they flower in perfection. By seedlings new varieties are principally gained, the roots of which furnishing Off-sets by which they are increased.

The separating Off-sets may be performed in some sorts every year, in others once in two or three years, according to the sorts, and the increase of Off-sets afforded by the main roots.

The proper seasons for separating or taking them off, in the bulbous- and many tuberous-rooted plants, are chiefly summer and autumn, when they have done flowering, and the leaves are decayed, as at that period the roots of these sorts, having had their full growth, assume an

inactive state, drawing little nourishment from the earth for a few weeks. It is also the only proper period for moving all the bulbous kinds in particular, both to separate Off-sets and transplant the main roots, or to take them up for keeping for a while. See BULB.

The roots should be taken up in dry weather if possible, and all the Off-sets separated singly from the main bulb, &c. planting them in nursery-beds, in rows six inches asunder, by dibble, or in drills two or three inches deep, or in any other method that may be suitable. They should remain a year or two, according to their size, in this situation to get strength; then be transplanted, at the proper season, where they are to continue, managing them as other bulbous- and tuberous-rooted plants. See BULB and TUBER.

The Off-sets of fibrous-rooted perennial plants, may either be slipped off from the sides of the main roots as they stand in the ground, or the roots may be wholly-taken up, and parted into as many slips as there are Off-sets properly furnished with fibres.

In this sort the proper season is autumn, when their stalks decay, or early in spring, before new ones begin to shoot forth; though some hardy sorts may be slipped any time in open weather from the autumn to the early spring, and others almost any time when they occur; planting them by dibble, the smaller ones in nursery-beds, in rows six or eight inches asunder, to have a year's growth; and the larger ones at once where they are to remain.

In several sorts of under-shrubby perennial plants that are capable of being increased by Off-sets from the bottoms, the proper season for taking them off is the autumn and spring, or in the hardy kinds any time in open weather, during the autumn or early spring, planting them in nursery-rows for a year or two, or till of proper size for the purposes they are designed for.

The Off-sets of succulent plants should generally be slipped off in summer, and, previous to planting those of the tender kinds, be laid on a dry shelf for some days, till the moisture at bottom is dried up; then planted in pots of dry soil, and managed according to their different kinds and habits of growth. See SUCCULENT PLANTS.

Off-sets are never produced from annual plants of any kind.

The particular management that is requisite in the different kinds is fully explained under the Culture of the plant to which it belongs.

OIL-TREE. See RICINUS.

OLD-MAN'S-BEARD. See CLEMATIS.

OLEA, a genus containing plants of the exotic tree kind. The Olive Tree.

It belongs to the class and order *Diandria Monogynia*, and ranks in the natural order of *Sepiaria*.

The characters are: that the calyx is a one-leaved perianthium, tubular, small, deciduous: mouth four-toothed, erect: the corolla one-petalled, funnel-form: tube cylindrical, the length of the calyx: border four-parted, flat: segments subovate: the stamina have two, opposite, awl-shaped filaments, short: anthers erect: the pistillum is a roundish germ: style simple, very short; stigma bifid, thickish, with the clefts emarginate; the pericarpium is a sub-ovate drupe, smooth, one-celled: the seed is a nut, ovate-oblong and wrinkled.

The species cultivated are: 1. *O. Europæa*, Common European Olive; 2. *O. Cupensis*, Cape Olive; 3. *O. Americana*, American Olive; 4. *O. fragrans*, Sweet-scented Olive.

The first grows naturally in woods in the South of France, Spain, and Italy, and is therefore not cultivated: the leaves are much shorter and stiffer than those of the cultivated Olive: the branches are frequently armed with thorns, and the fruit is small and of little use.

There are several varieties; as the Warty Olive, which is a native of the Cape. The Long-leaved, which is chiefly cultivated in the South of France, and from which they make the best oil. The young fruit is the most esteemed when pickled.

There are several sub-varieties. The Broad-leaved, which is chiefly cultivated in Spain, where the trees grow to a much larger size than the preceding; the leaves are much larger, and not so white on their under side: the fruit is near twice the size of the Provence Olive, but of a strong rank flavour, and the oil is likewise strong.

There are also other varieties; as the narrow-leaved, short hard-leaved, shining-leaved, African, Lucca, &c.

It is observed that the Olive seldom becomes a large tree; but two or three stems frequently rise from the same root, from twenty to thirty feet high, putting out branches almost their whole length, covered with a gray bark: the leaves are stiff, about two inches and a half long, and half an inch broad in the middle, gradually diminishing to both ends, of a lively green on their upper side and hoary on their under, standing opposite: the flowers are produced in small axillary bunches; they are small, white, and have short tubes spreading open at top: the fruit is a su-

perior-berried drupe, of an oblong spheroidal form, and of a yellowish green colour, turning black when ripe.

The usual method of making oil from Olives in Italy is, to crush the fruit to a paste with a perpendicular mill-stone running round a trough; which is then put into flat round baskets, made of rushes, piled one upon another under the press: after the first pressure, scalding water is poured into each basket, its contents stirred up, and the operation repeated till no more oil can be skimmed off the surface of the tubs beneath: but this is not a good method; the oil is seldom pure, keeps ill, and soon grows rancid: but by another process, which is that of pounding the fruit in a mortar, the crushed substance being then thrown into a long woollen bag, and rubbed hard upon a sloping board, and then wrung, adding afterwards hot water, and continuing to press as long as a drop of oil can be drawn, the work is much more effectually performed.

The unripe Olives when pickled, especially the Provence and Lucca sorts, are to many extremely grateful, and supposed to excite appetite and promote digestion. According to Miller they are prepared by repeatedly steeping them in water; to which some add alkaline salt or quick-lime, in order to shorten the process; after which they are washed, and preserved in a pickle of common salt and water, with sometimes the addition of an aromatic.

The best salad oil is of a bright pale amber colour, bland to the taste, and without the least smell.

It has been observed that, with a little protection in severe frost, the Olive-tree may be maintained against a wall about London, but that in Devonshire there are some of these trees which have grown in the open air many years, and are seldom injured by frost, yet the summers are not warm enough to bring the fruit to any great perfection.

The second species is a small tree, or rather shrub, not branching much: the trunk straight, with many joints; bark subhirsute, blackish brown, with ash-coloured dots and lines: the leaves conjugate, decussate, sometimes sinuated at the end, but commonly entire, dense, and rigid, moderately concave, paler or deeper green, but always paler underneath, with oblique smooth veins, less conspicuous underneath than above: from the axils and at the end of the branches the flowers come out in racemes in June and July, sometimes thinly disposed, but sometimes so numerous that the racemes hang down. It is a native of the Cape.

The third has the leaves opposite, evergreen,
VOL. II.

petioled, shining: the racemes short, axillary, brachiate, with opposite pedicels: the segments of the corolla revolute: the style so short as to be scarcely any: the stigma bifid: the drupe globular, even, handsome: the nut obovate, substriated, perforated at the base: and there are male and female flowers on the same plant with the hermaphrodites. It is a native of Carolina and Florida, flowering in June.

The fourth species is a large tree in its native situation, the branches and branchlets trichotomous, obscurely four-cornered, smooth: the leaves decussate, oblong, sharp, a little bent back at the edge, parallel-nerved, reticulated, smooth, deep green above, paler underneath, spreading, frequent on the branchlets, a finger's length: the petioles semicylindric, grooved, smooth, a quarter of an inch in length: the flowers on the branchlets, aggregate in umbels, about six or eight together; peduncles filiform, one-flowered, smooth, half an inch in length: the flowers are very sweet-scented. It is a native of China, &c., flowering in July and the following month.

Culture.—These plants may be propagated in this climate by layers, which should be made from the young branches in the spring, in the usual manner, and be occasionally watered during the summer season, when in the autumn following they may be taken off and be planted in separate pots, being duly watered and placed in proper shade till fresh rooted, removing them in the beginning of the autumn into the shelter of the green-house. The layers sometimes, however, require two summers before they become perfectly rooted.

It is notwithstanding the best method to purchase plants of this sort, which are annually sent to the Italian warehouse-men in London, of pretty large sizes, with orange and other trees, as they are very tedious in raising from layers.

These plants, after being thus procured, and cleaned from filth by soaking their roots in water, should be planted in pots filled with fresh sandy light earth, plunging them in a moderate hot-bed, shading them in the hot sun, and refreshing them occasionally with slight waterings as the earth in the pots becomes dry. When they begin to shoot they should have air admitted pretty freely in proportion to the weather, being afterwards inured to the open air in a place defended from winds, removing them in the beginning of autumn into the green-house.

When they have in this management acquired strong roots, they may be removed with earth about them, and be planted out in the open ground in a dry warm situation, being managed as myrtles and other similar plants. When

covered by mats in the winter frost, great care must be taken to prevent their becoming mouldy, by not letting them remain covered too long, without the air being admitted.

They flower and produce fruit sometimes in two or three years.

They all afford variety among other greenhouse plants as well as in other situations.

OLIVE. See OLEA.

ONONIS, a genus containing plants of the shrubby kind.

It belongs to the class and order *Diadelphia Decandria*, and ranks in the natural order of *Papilionaceæ* or *Leguminosæ*.

The characters are: that the calyx is a five-parted perianthium, almost the length of the corolla: segments linear, acuminate, slightly arched upwards; the lowest under the keel: the corolla is papilionaceous: banner cordate, striated, depressed at the sides more than the other petals: wings ovate, shorter by half than the banner: keel acuminate, as long as or longer than the wings: the stamina have ten filaments, connate in an entire cylinder: anthers simple: the pistillum is an oblong germ, villose: style simple, rising: stigma blunt: the pericarpium is a rhomb-shaped legume, turgid, subvillose, one-celled, two-valved, sessile: the seeds few and kidney-form.

The species principally cultivated are: 1. *O. Natrix*, Yellow-flowered Shrubby Rest-harrow; 2. *O. tridentata*, Three-tooth-leaved Rest-harrow; 3. *O. fruticosa*, Shrubby Rest-harrow; 4. *O. rotundifolia*, Round-leaved Rest-harrow.

There are other species both of the annual and perennial kinds, that may be cultivated for variety.

The first is a very strong-smelling plant, with a resinous odour, and not very clammy: the leaves oval, flattish, serrate only at the top, not fleshy: the peduncle the length of the awn: root large and wrinkled: the stems more or less upright, commonly a foot high: leaflets oblong, villose, toothed at the end: the flowers large, yellow, solitary, on a peduncle elbowed at two-thirds of its length, whence springs a thread like an awn: the upper part of the flower is rayed with red lines: legumes oblong and villose. It is a native of the South of France, &c.

The second species has erect shrubby stalks, a foot and a half high, dividing into slender branches very full of joints: the leaflets are narrow, thick, fleshy, on short footstalks: the flowers at the ends of the branches in loose panicles, some of the peduncles sustaining two and others but one flower: they are of a fine purple colour, and appear in June; the seeds

ripening in September. It is a native of Spain and Portugal.

The third species is a very beautiful low shrub, rising with slender stalks about two feet high, dividing into many branches: the flowers come out in panicles at the ends of the branches upon long peduncles, which for the most part sustain three large purple flowers: the legumes are turgid, about an inch long, hairy, inclosing three or four seeds. It is a native of the South of France, flowering in May and June.

It varies with white flowers.

The fourth has the stem round, striated, somewhat villose, a foot and half or two feet in height: the leaves are petioled, serrate-toothed, with the teeth alternately larger and smaller, villose, large; the end leaflet larger and rounder than the others: the stipules green, sheathing, absolutely serrate, with longitudinal prominent nerves: the flowers form handsome bunches at the ends of the branches; they are on a long peduncle, frequently three together, each on its proper pedicel, of a purple colour. It is a native of Switzerland, flowering from May to July.

Culture.—These plants may be increased by seeds, cuttings, and slips, according to the different kinds.

The seeds of the first sort should be sown upon beds of light earth in the early spring, as about April, thinly in drills, when they should be properly thinned out during the summer months, and kept perfectly free from weeds; when in the beginning of the autumn they may be removed into the places where they are to remain. It may likewise be increased by cuttings planted out at the same time.

Though this sort is pretty hardy when the winters are not very severe, a few plants should always be kept in the greenhouse. And as it is apt to grow out of form it should be kept well cut in, and new plants be frequently raised from seeds.

These plants cannot be preserved in pots. They flower the second year.

The second sort should have the seeds sown in pots and placed in a mild hot-bed, or on a very warm sheltered border, in the early spring; but the first is the best method, the plants being afterwards managed as tender plants, having either the protection of the greenhouse or of mats.

The third sort is raised from seeds sown either in pots or warm borders in the early spring months. It succeeds best in shady situations where the soil is of a sandy quality. The potted plants are often introduced in greenhouse collections; but they are capable of with-

standing the severity of most winters in the open air.

The fourth sort should have the seeds sown in the early spring on an open border, the plants being afterwards properly thinned and kept clean from weeds. It may likewise be raised from slips planted out at the same season. It is very hardy, and requires little trouble in its cultivation. They are all plants which afford ornament and variety in the borders, or among other potted plants of the green-house kind.

OPHIOXYLUM, a genus containing a plant of the shrubby climbing kind.

It belongs to the class and order *Polygamia Monoecia*, and ranks in the natural order of *Apocineae*.

The characters are: that in the hermaphrodite flowers, the calyx is a five-cleft perianthium, acute, erect, very small: the corolla is one-petalled, funnel-form: tube long, filiform, thickened in the middle: border five-parted, spreading a little, without a nectary: the stamina have five filaments, very short, in the middle of the tube: anthers acuminate: the pistillum is a superior germ, roundish: style filiform, the length of the stamens: stigma capitate: the pericarpium is a berry twin, two-celled: the seeds solitary, roundish. Male flowers on the same plant: the calyx as in the hermaphrodites (bisid): corolla one-petalled, funnel-form: tube long: border five-cleft: nectary in the mouth of the corolla, cylindric, quite entire: the stamina have two filaments, very short: anthers acuminate, converging within the nectary.

The species is *O. serpentinum*, Scarlet-flowered Ophioxylum.

It has the stem upright, round, quite simple: the leaves in fours placed cross-wise, lanceolate-ovate, smooth, acuminate, petioled: nectary like that of narcissus; but according to Burmann the stem is three-cornered, jointed, striated; at each joint are three leaves, which are oblong acuminate, entire not serrate, in which they differ from those of the peach-tree, whose form they resemble: petioles short: at the top of the stem are many florets in a sort of umbel; and Jussieu describes it as a shrub with three or four leaves in whorls; flowers glomerate, terminating, males mixed with the hermaphrodites, two-stamened only, with a cylindric entire crown at the throat of the tube, without any germ: the berry fleshy, two-lobed, within a very small three- or five-cleft calyx, lenticular-compressed, two-celled, of a brick-red: it is a native of the East Indies, flowering in May and the following month.

Culture.—This may be raised by seeds, which should be sown in pots in the early spring and be plunged in a bark hot-bed, and when the

plants have attained some growth, removed into separate pots and re-plunged in the bark hot-bed of the stove, where the plants must be constantly kept. It may likewise be increased by layers and cuttings, which should be laid down or planted out at the same season and have the same sort of management as those procured from seeds.

They are ornamental stove plants.

OPHRYS, a genus comprising plants of the bulbo-fibrous-rooted perennial kind.

It belongs to the class and order *Gynandria Diandria*, and ranks in the natural order of *Orchidaceae*.

The characters are: that the calyx has wandering spathes: spadix simple: perianthium none: the corolla has five oblong petals, converging upwards, equal; two of these exterior: nectary longer than the petals, hanging down, posteriorly one somewhat keeled: the stamina have two filaments, very short, placed on the pistil: anthers erect, covered with the inner margin of the nectary: the pistillum is an oblong germ, contorted, inferior: style fastened to the inner margin of the nectary: stigma obsolete: the pericarpium is a subovate capsule, three-cornered, blunt, striated, three-valved, one-celled, opening at the keeled angles: the seeds numerous, like saw-dust: the receptacle linear, fastened to each valve of the pericarpium.

The species cultivated are: 1. *O. ovata*, Common Ophrys or Twayblade; 2. *O. spiralis*, Spiral Ophrys, or Triple Lady's Traces; 3. *O. nidus avis*, Bird's-nest Ophrys; 4. *O. muscifera*, Fly Ophrys; 5. *O. apifera*, Bee Ophrys; 6. *O. aranifera*, Spider Ophrys; 7. *O. monorchis*, Yellow or Musk Ophrys; 8. *O. anthropophora*, Man Ophrys.

The first has a perennial root, consisting like the third of numerous thick fleshy bundled fibres, and renewed every year: the stem from twelve to eighteen inches, and even two feet in height, below the leaves much thicker than above, and naked; above the leaves downy; the lower part of the stem immediately above the root is clothed with a membranaceous spathe of two or three leaves; about one-third of the height of the stem are placed two very broad ovate leaves, one embracing the other at the base, marked with about seven nerves, and much resembling the leaves of the broad plantain; above these are two or three very short ovate, acuminate stipules: the flowers numerous, in a loose spike, four inches long or more, yellowish green. The flowers have a fragrant musky scent. It is a native of most parts of Europe.

It varies with three leaves.

The second species has from one to three bulbs, or sometimes four, varying from oblong, and half

an inch in length, to cylindrical and an inch and half long, rough or villose, pointed, and furnished with a few fibres: the stem from six to nine inches high, the lower part smooth, the upper downy: the root-leaves four or more, forming a tuft, ovate-lanceolate, smooth, entire at the margins, bright green, half an inch in breadth, dotted when magnified, and faintly ribbed. By the side of these, and not from amongst them, arises the stem, clothed with three or four lanceolate, acuminate, embracing leaves, downy, and membranous at the edge: the spike from two to four inches long, twisted in a spiral form, with numerous (fifteen or more) flowers, growing from one side, and following its spiral direction. It is a native of many parts of Europe, flowering from August to October.

The third has the root composed of many strong fibres, from which arise two oval veined leaves, three inches long, and two broad, joined at their base; between these springs up a naked stalk about eight inches high, terminated by a loose spike of herbaceous flowers, resembling gnats, composed of five petals, with a long bifid lip to the nectarium, a crest or standard above, and two wings on the side. It is a native of many parts of Europe.

The fourth species has the bulbs roundish: the stem from nine to fifteen inches high: the leaves three or four, sheathing the stem at the base, lanceolate, pale green, smooth, shining, marked with numerous longitudinal nerves, the intermediate space covered with a thin somewhat pellucid puckered skin, giving them a silvery hue: the upper part of the stem naked, yellowish green, nearly round, smooth: the bractes linear-lanceolate, much longer than the germ, pale yellowish green: the flowers in a long thinly scattered spike; sometimes fifteen in number, but seldom more than four or five: it has much resemblance to a fly. It is a native of Sweden, &c. It flowers in May and June.

There are several varieties, as the fly-shaped; the great fly; the large green fly; the blue fly; and the yellow fly.

The fifth has the stem about a foot high, leafy, round except between the fructifications, where it is compressed: the leaves alternate, lanceolate, sheathing, pubescent, nerved: the bractes longer than the germs, lanceolate. The three outer petals large, spreading, purple, with the keel and two nerves green; the two inner petals very small, hairy, reflex, green: the lower lip of the nectary large, wide, but shorter than the petals, dusky purple mixed with yellow, three-lobed, the side-lobes smaller, hairy, reflex, triangular, acuminate; the middle one very large, pubescent, three-lobed, bent down, the middle segment

longer, acuminate; upper lip narrowed above with a point, longer than the lower lip, of a green colour: the filaments long: anthers very large: the germ longer than the petals, but shorter than the bracte, large, deeply grooved. It is a native of Europe, flowering in June and July.

The sixth species has the stem six inches high, more or less according to its place of growth, round, smooth, covered below with leaves embracing it: the leaves next the root an inch and half long, almost an inch broad, ovate-lanceolate, somewhat blunt, marked with impressed lines, smooth, spreading on the ground; those of the stalk few, narrower and more pointed: the flowers from three to six, in a thin spike. It is a native of Britain, flowering in June.

It is fancied by some to resemble a bee, by others a spider; from the breadth of the lip, and its being marked with different shades of brown, it derives its resemblance to the latter. Others have discovered a likeness to a small bird in the flower.

The seventh has a single bulb, round or somewhat oblong, with a few thick fibres from the crown: the stem about six inches high, round and smooth: the root-leaves two or three, sheathing the stem, lanceolate, acute, smooth, of a shining yellowish green, marked with parallel veins: on the stem one or two sessile awl-shaped leaves: spike an inch or an inch and half long, of numerous flowers, which are greenish yellow, with a faint musky smell. It is a native of many parts of Europe; Sweden, Denmark, &c., flowering in July.

The eighth species has a stem about a foot high, firm, smooth, round at the base, somewhat angular upwards: the root-leaves four or five, sheathing the stem at the base, lanceolate but varying in breadth, spreading: above these one or two more, closely embracing the stem: the flowers numerous, in a long loose spike. They vary in number from ten to fifty. The lip of the nectary is so divided as to bear a coarse resemblance to the human arms and legs, whence it has been named *Man Orchis*. It is a native of the southern parts of Europe, and England, flowering in June.

It varies in size, and in the colour of its flowers, from yellow green to bright ferruginous.

Culture.—All these plants may be introduced into the different parts of pleasure-grounds from the places where they grow naturally in this country, and be preserved; but they do not admit of being propagated in them; the proper period for this purpose is just before the stalks decay, in the latter end of summer or beginning of the autumn, as at that season the bulbs will be in the best state for growing strong and flowering the following

year. The roots should be taken up with large balls of earth round them, and be planted again as soon as possible. They should also be placed as as that the soils and situations may be as nearly as possible similar to those from which they were taken; those taken from woods being planted out in shady situations; those from boggy or marshy places, in the more moist and boggy parts; and those from dry elevated situations, in such as have the greatest degrees of dryness and are the most open. They should afterwards be as little disturbed as possible by any sort of culture;—with this sort of management the roots will often continue for several years, flowering annually during the summer.

In the culture of the sixth sort Mr. Curtis succeeded, by taking them up from their natural situations when in flower, and baring their roots no more than was necessary to remove the roots of other sorts of plants; then filling large-sized garden-pots with three parts good moderately stiff loam and one part chalk mixed well together, passing them through a sieve somewhat finer than a cinder sieve, afterwards planting the roots in them to the depth of two inches, and, where there is more than one, three inches apart, watering them occasionally during the summer season in dry weather, and on the approach of winter placing the pots under the protection of a frame and glasses in order to prevent their being injured by wet or frosts.

They all afford variety, and are highly ornamental in the clumps, borders, and other parts of shrubberies, &c.

ORCHARD, a portion of garden-ground set apart for the growth of different sorts of the more common sorts of fruit, but mostly that of the apple kind. The trees in this case are mostly of the standard kind, especially when large supplies of fruit are wanted, and generally consist of Apple-trees, Pear-trees, Plum-trees, and Cherry-trees; and, to render it more complete, should contain Quinces, Medlars, Mulberries, Service-trees, Filberts, Spanish Nuts, and Barberries, as well as Walnuts and Chestnuts. As the two last sorts are well adapted for sheltering the others from high winds, they should, Mr. Forsyth thinks, be planted in the boundaries of the orchard, a little closer than ordinary, for that purpose.

In providing trees, especially of the apple kind, for this purpose, too much care cannot be taken to admit of none but such as have good roots, fair clean stems, and proper heads; and at the same time attention should be paid that a proper assortment of the different sorts be procured for the supply of the table during the whole year, a few of the Summer sorts are sufficient, but more

of the Autumn, and still a larger quantity of the Winter kind will be necessary; as upon this last sort the chief dependence must be placed from the beginning of the year till nearly the period of the fruit being ready again.

In districts where the process of cyder-making is conducted upon a large scale, large orchards of apples only are often met with; and in some counties, as Kent, there are orchards wholly of Cherries, or these and Filberts. In general, however, there ought to be a much larger proportion of Apples than of any other fruit in orchards, as in proper situations they are very profitable; and, in addition, the trees have a delightful appearance when in blossom, as well as when the fruit is ripe.

Situation and Soil.—In respect to situation, an orchard should rather be elevated than low, as on a gentle declivity; open to the south and south-east, to give free admission to the air and rays of the sun, as well as dry up the damps and disperse the fogs, in order to render the trees healthy, and give a fine flavour to the fruit. It should likewise be well sheltered from the east, north, and westerly winds, by suitable plantations, where not naturally sheltered by hills or rising grounds. Such plantations, when they consist of forest-trees, should neither be too large nor too near the orchard; as where that is the case they prevent a free circulation of air, which is injurious to the trees. Where the ground does not admit of such plantations, Mr. Forsyth advises planting cross rows of fruit-trees, in the manner directed in gardens, as well as some of the largest-growing trees nearest the outsides exposed to those winds, two or three rows of which should, he says, be planted closer than ordinary, which would greatly shelter those in the interior parts of the Orchard, and be of great service, in addition, to the walnut and chestnut trees, as mentioned above.

Orchards are planted on many different sorts of soil and succeed well; but a dry friable loam is probably the most suitable, as trees of this sort are impatient of moisture. Such as have been mentioned for gardens will answer perfectly well, and such as produce good crops of corn, grass, or other vegetables, are mostly proper for an Orchard; and though the above sort is to be preferred, any of a good quality, not too light or dry, nor wet, heavy, or stubborn, but of a moderately soft and pliant quality, will be found to answer the end perfectly. The shingly and gravelly soils disagree very much with fruit-trees, unless there be loam intermixed with them. They succeed much better on a chalk bottom, or subsoil. On such a soil, Mr. Forsyth has

seen roots twelve feet deep, and the trees thrive well. Where the bottom is clay, the roots should, he says, be cut-in once in four years, to prevent them from penetrating the clay, which would greatly injure the trees. Whatever the nature of the soil may be, it should have a good depth, as two or three feet. Where the soils are wet they should be well drained in the same manner as has been directed for gardens, or by forming the land in ridges with furrows between the rows to convey off the moisture, the turf being relaid in case of the ground being in the state of sward.

Size.—In regard to the size of an Orchard, it may vary from one to ten and fifteen or more acres, according to the quantity of fruit wanted, or the proportion of ground that is fit for the purpose.

Preparation.—This is effected in different ways: but the best method is, probably, before planting the trees, to trench it two spits deep, and ten feet broad, where the rows are to be planted, and to loosen a spit below, unless it be clay, which should, Mr. Forsyth says, be trodden down. Where the ground is in pasture, it should, he says, be ploughed, and well summer-fallowed, till the grass be killed, otherwise when it is laid in the bottom in trenching, which it generally is, it will be very apt to breed grubs, which do much mischief. In bad shingly or gravelly soils, he recommends that holes should be dug at least three feet deep, and filled up with good mould: if mixed up with rotten dung, rotten leaves, or other manure, the trees will in time amply repay the expense: the dung used for this purpose should, he says, be that from the melon and cucumber beds, mixed with the mould from the same, when the beds are broken up in autumn, or winter; and be laid up in heaps, and continued so for one year at least; but be frequently turned and have some good fresh mould mixed with it. It is the practice with some to only dig holes large enough to receive the roots, especially in grass-ground which is to be continued so. Others prepare the ground by deep ploughing, if the Orchard is to be of great extent. The sward, if pasture, should be ploughed-in some time in spring; a good summer-fallow should be given it, ploughing it two or three times, which will rot the turf. A fortnight or three weeks before planting, it should have a good deep ploughing to prepare it for the reception of the trees. In Kent, and some other hop districts, they prepare their orchard-ground by the growth of hops upon it with the fruit-trees, by which they are much protected and brought forward.

Season of Planting.—In relation to the period of planting, it may be performed with success at different seasons, according to the nature of the land. The best time for planting on a dry soil is, Mr. Forsyth says, in October; but, if wet, the latter end of February, or the month of March, will be a more fit season. The chief circumstance in this business is to suit the trees as much as possible to the soil, and to plant them at proper distances from each other; which may be from forty to eighty feet, according to the size of the trees when full grown. He observes that fruit-trees, when planted too thick, are very liable to blights, and to be covered with moss, which robs them of a great part of their nourishment, besides spoiling the flavour of the fruit.

Procuring the Trees.—In providing the trees it is a good practice to procure them from a soil nearly similar to, or rather worse than, that where they are intended to be planted; as trees transplanted from a rich soil to a poorer one never thrive so well; but if from a poor to a richer soil, they generally succeed in a perfect manner. Good trees, which have been properly pruned, which are quite free from bruises and disease, should always be carefully selected; and their roots be preserved as much as possible when taken up.

The most proper sorts of trees for small orchards may be those of the Jancting, Golden Pippin, Nonesuch, Ribston Pippin, Nonpareil, Queen, Sky-house, Golden Rennet, Aromatic Pippin, Grey Leadington, Scarlet Pearmain, Lemon Pippin, Pommegrise, French Crab, Russeting and Codling kinds. But various other sorts may be employed where the orchards are extensive, and a great variety of fruit necessary.

Planting the Trees.—With regard to the proper distance of planting the trees, it should be regulated by the natural growth or spreading of them when fully grown, as well as the nature and goodness of the soil. It was formerly the practice to have them put in at narrow distances; but at present ten, twelve, or fifteen yards are more common, and in the cyder districts from twenty to twenty five yards are in use. The usual mode of arranging the trees is, in open grounds in lines or rows; but in close plantations the quincunx method is more in use. In the row method, when it can be done, they should be in the direction of north and south, or one point more to the east, as by this means they will have the advantage of the sun from the early part of the morning in the spring season, which will in a great measure prevent the damp

fogs from hanging upon them and hindering the due increase of the fruit.

In the act of planting or putting them into the ground, great care should be taken that they are not put in to too great a depth, as where that is the case they are in great danger of being destroyed. It is also necessary that a bed of fine good mould be provided for them, and that it be carefully put in with them, so as to be properly insinuated among the fibres of the roots, and afford them due support; the whole being carefully trodden round the plants in finishing the business.

Upon this being performed in a proper and perfect manner, and the young trees afterwards kept perfectly steady by suitable supports, the success of the planter in a great measure depends.

Where the trees are planted in the quincunx order, and at the distance of eighty feet, Mr. Forsyth says, "the ground between the rows may be ploughed and sown with wheat, turnips, &c. or planted with potatoes: the ploughing or digging the ground, provided it be not done so deep as to hurt the roots, by admitting the sun and rain to meliorate the ground, will, he thinks, keep the trees in a healthy flourishing state. It will be necessary to support the young trees by tying them to stakes until they are well rooted, to prevent their being loosened or blown down by the wind.

"In the spring after planting, if it prove dry, some turf should be dug and laid round the stems of the young trees with the grassy side downwards; which will keep the ground moist, and save a deal of watering: if the trees have taken well, this need not be repeated, as they will be out of danger the first year. The turf should be laid as far as the roots of the trees are supposed to extend; and when it is rotted it should be dug-in, which will be of great service to their roots.

"Such trees as are of very different sizes when full grown should not, he says, be planted promiscuously; but, if the soil be properly adapted, the larger planted in the back parts or higher grounds, or at the north ends of the rows, if they run nearly north and south, and the others in succession according to their size. The trees when planted in this manner will have a fine effect when grown up; but if they are planted promiscuously, they will not appear so agreeable to the eye; and, besides, the smaller trees will be shaded by the larger, which injures them, and spoils the flavour of the fruit.

"It is advised that Orchards should be dunged once in two or three years with some sort of good manure, as this is of much advantage in rendering them fruitful and productive.

"The stems of trees in those where cattle feed should be high enough to prevent their eating the lower branches; and fenced in such a manner as to prevent their being barked, or injured by the cattle rubbing against them, particularly when young; which may be done by triangles of wood, or the trees may be bushed with thorns.

But in orchards where cattle are not permitted to go, Mr. Forsyth prefers "dwarf-trees to standards, taking care to proportion the distance of the rows to the size of the trees."

After-Management.—This chiefly consists in keeping the trees properly pruned and cut-in; as where this is judiciously done the trees will come into bearing sooner, and continue in vigour for nearly double the common time. But with these standard-trees less culture is necessary than in other cases. No branch should ever be shortened, unless for the figure of the tree, and then it should be taken off close at the separation. The more the range of branches shoot circularly, a little inclining upwards, the more equally will the sap be distributed, and the better the tree bear. The ranges of branches should not be too near each other, that the fruit and leaves may not be deprived of their full share of sun; and where it suits, the middle of the tree should be so free from wood, that no branch may cross another, but all the extremities point outwards.

About October or November, or as soon as the fruit is removed, is the most proper season for this work. It is the best practice to take off superfluous branches with a saw, and afterwards to smooth the place with a knife; for it is essential that every branch which is to come off should be cut perfectly close and smooth. The wounded part may then be smeared over with a proper composition. Such branches should always be taken off as come near to the ground, that have received any material injury, where the leaves are much curled, or that have a tendency to cross the tree or run inwards. And a little attention may be given to the beauty of the head, leaving all the branches as nearly equidistant as possible. Where there are any remaining blotches, they should be opened or scored with a knife; and where the bark is ragged from any laceration, it should be pared gently down to the live wood: touching over each with a proper composition. This being done, the moss should be rubbed clean off, and the trees scored. In this last operation, care should be taken not to cut through the inner or white rind, which joins the bark to the wood. When trees are much thinned, they are subject to throw out great quantity of young shoots in the spring, which

should be rubbed off, and not cut, as cutting is apt to increase the number.

The great enemy to orchards where apples are grown, is Mistletoe, and is often permitted to become very injurious to them. The usual method of clearing trees from it, is to pull it out with hooks in frosty weather, when brittle, and readily broken off from the branches. A labourer is capable of clearing fifty or sixty trees in a day.

Moss, moist spring frosts, blights, and several other similar causes are highly injurious to this sort of tree, as is shown under these particular heads.

ORCHIS, a genus containing plants of the hardy herbaceous bulbous-rooted flowery perennial kind.

It belongs to the class and order *Gynandria Diandria*, and ranks in the natural order of *Orchideæ*.

The characters are: that the calyx is a wandering spathe: spadix simple: perianthium none: the corolla has five petals; three outer, two inner, converging upwards into a helmet: nectary one-leafed, fastened to the receptacle by the lower side between the division of the petals: upper lip erect, very short; lower lip large, spreading wide: tube behind horn-shaped, nodding: the stamina have two filaments, very slender, very short, placed on the pistil: anthers obovate, erect, covered with a bilocular folding of the upper lip of the nectary: the pistillum is an oblong germ, twisted, inferior: style fastened to the upper lip of the nectary, very short: stigma compressed, blunt: the pericarpium is an oblong capsule, one-celled, three-keeled, three-valved, opening three ways under the keels, cohering at the top and base: the seeds numerous, very small, like saw-dust.

The species cultivated are: 1. *O. bifolia*, Butterfly Orchis; 2. *O. morio*, Female or Meadow Orchis; 3. *O. mascula* Male or Early Spotted Orchis; 4. *O. militaris*, Man Orchis; 5. *O. latifolia*, Broad-leaved or Marsh Orchis; 6. *O. maculata*, Spotted Orchis; 7. *O. conopsea*, Long-spurred Orchis; 8. *O. abortiva*, Purple Bird's Nest, or Bird's Nest Orchis.

The first has ovate bulbs, tapering to a point at the base, white within and without; thick fleshy fibres come out above them from the base of the stem: the stem a foot or eighteen inches high, smooth, six-angled, three ribs running down from each leaf: leaves usually two, (sometimes three,) springing from the root, ovate, blunt, tapering at the base, five or six inches long, and from two to three inches wide, smooth, pale green above, silvery beneath, marked with numerous parallel veins: on the stem are three

or four lanceolate, sessile leaves, the lowest of which are longest: the flowers are numerous in a long loose spike. It is a native of Britain, &c.

The second species has roundish bulbs, the size of a hazel-nut or of a nutmeg, one fixed to the base of the stem, and the other connected to the base by a fibre half an inch long, and the thickness of packthread: above them are largish spreading fibres: the stalk from six or seven inches to a foot or more in height, upright and leafy: the leaves embracing, lanceolate, marked with lines, glaucous, shining on the upper side, underneath silvery; the bottom ones for the most part turning back and variously contorted: the flowers few, from six to eight, seldom more than twelve, purple, sitting loosely on the stalk. It is a native of this country.

There are varieties with purple flowers, with red flowers, with violet flowers, with flesh-coloured flowers, and with white flowers.

The third has large, oval bulbs, both fixed to the base of the stem, which is about a foot high, round, smooth, upright, solid, above naked and purplish, below clothed with surrounding leaves; these are lanceolate, alternate, broadish, the lower ones sheathing at the base, spreading upwards, bright green and shining above, glaucous beneath, marked longitudinally with parallel veins, and usually spotted with large brown or dark purple spots: the upper leaves closely sheath the stem, and are pale green: the flowers in a loose spike, numerous. It is a native of England.

The fourth species has the stem about one foot high, round and smooth: the leaves about four, sheathing, acutely lanceolate, the three lower spreading, the upper one closely embracing, bright green, with numerous parallel veins: the spike from one to two inches long, with numerous flowers: bractes very short, membranaceous, oval but pointed, and terminated with an awn: petals all convergent, three exterior large and broad, oval-lanceolate, acute, two interior, narrow, linear or somewhat awl-shaped, all greenish white with purple lines: lip of the nectarium purplish, or white with purple dots, long and narrow, divided into three segments, the two outer near the upper part linear, half as long as the lip, the lower again slightly divided into three, the two outer broader, rounded, slightly serrate, the middle one appearing like a spine: horn blunt, half as long as the germ: cases to the anthers distant: the anthers yellow. It is a native of Britain.

There are several varieties.

The fifth has broad and flat bulbs, divided into a few fingers, which sometimes run out into a long

fibre, striking downwards; several short thick fibres also shoot out laterally from the top of the bulbs: the stem about a foot (or eighteen inches) high, smooth, hollow, somewhat angular towards the top: the leaves five or six, alternate, sheathing the stem to the spike, acutely lanceolate, keeled and marked with parallel veins, pale green, rarely spotted, and when so, very obscurely; the bractes much longer than the flowers, resembling the uppermost leaves, acutely lanceolate, green, sometimes with a tinge of purple: the flowers very numerous (forty), in a close somewhat conical spike, for the most part rose or flesh-coloured with us, often purple, rarely white. It is a native of Europe, flowering at the end of May.

There are different varieties.

The sixth species has palmated, compressed bulbs, with the segments much divaricated: stem solid, from seven or eight to eighteen inches high, the lower part round, the upper somewhat angular: the lower leaves embracing the stem, lowest constantly short, broad and blunt, the next considerably longer, bluntly lanceolate; above these more acutely lanceolate; upper ones very narrow and apparently sessile, but the margins are decurrent, whence the angular appearance of the stem; beneath they are silvery green, with parallel green nerves, above pale green, often partially covered with the same silvery skin, marked with numerous reddish brown spots, mostly oval and transverse, but sometimes irregular: the flowers numerous (forty) in a close conical spike. It is a native of Europe.

It varies with purple flowers, red flowers, and white flowers.

The seventh has palmated, compressed bulbs; the stem twelve to eighteen inches high, smooth and firm, round below; angular upwards; lower leaves sheathing the stem, long, narrow, and acutely lanceolate, bright green, shining, keeled, with a strong midrib, on each side of which are two or three faint veins and one strongly marked: the lower stem-leaves embracing, upper sessile, lanceolate, acute, decreasing in size till they resemble the bracte: the flowers flesh-coloured or pale purple, (forty-two) in a loose spike, three inches long, smelling very sweet. It is a native of Europe.

The eighth species has the roots composed of thick horizontal fibres wrinkled transversely: the stem straight, upright, eighteen inches or more in height, blue or violet, leafless but sheathed with scales: the flowers in a very long thin spike, violet. It is a native of France, &c.

The whole plant is of a violet or deep purple colour.

VOL. II.

Culture.—These curious plants may all be introduced and preserved in the pleasure-grounds, by proper care in removing them from their native situations, which should always be done when their leaves decline, being previously marked. When removed at other seasons, they seldom succeed.

They should be taken up with balls of earth about their roots, and be immediately replanted, in a soil and situation as nearly as possible the same as that from which they were taken. When thus managed, they continue many years flowering in a strong manner.

They afford much variety where the different kinds are introduced in the borders and other parts.

ORIGANUM, a genus affording plants of the herbaceous annual and under-shrubby perennial kinds.

It belongs to the class and order *Didymia Gymnospermia*, and ranks in the natural order of *Verticillatæ*.

The characters are: that the calyx is a spiked involucre, composed of imbricate, ovate, coloured bractes: perianthium unequal, various: the corolla one-petalled, ringent: tube cylindrical, compressed: upper lip erect, flat, blunt, emarginate: lower trifid, the segments almost equal: the stamina have four filiform filaments, the length of the corolla, of which two are longer: anthers simple: the pistillum is a four-cleft germ: style filiform, inclined to the upper lip of the corolla: stigma very slightly bifid: there is no pericarpium: calyx converging, fostering the seeds at bottom: the seeds four, ovate.

The species cultivated are: 1. *O. vulgare*, Common Marjoram; 2. *O. onites*, Pot Marjoram; 3. *O. majorana*, Sweet or Knotted Marjoram; 4. *O. heracleoticum*, Winter Sweet Marjoram; 5. *O. Ægyptiacum*, Egyptian Marjoram; 6. *O. dictamnus*, Dittany of Crete or Candia.

The first has a perennial, creeping, horizontal, brown root, tufted with numerous fibres: the stem a foot, eighteen inches, or near two feet in height, upright, somewhat woody, a little downy, and often tinged with purple: the branches opposite, upright, more tender than the stalk, in other respects similar: the leaves are ovate, pointed, finely and thinly toothed, above nearly smooth, beneath downy, dotted on both sides, the edges finely ciliate, spreading: the petioles downy: axils of the leaves, in the cultivated plant, bear numerous smaller leaves. It is an aromatic and ornamental plant, growing wild in thickets and hedges, chiefly in a calcareous soil; and flowering from the end of June through the following month. It is found in most parts of Europe.

There are varieties with white flowers and light-green stalks; with purple flowers and with variegated leaves; which is sometimes cultivated in gardens, under the title of *Pot Marjoram*, used in soups.

The second species has the habit of Sweet Marjoram, but it is woody: the stems woody, perennial, a foot and half high, branched, spreading with long hairs: the leaves small, sessile, acute, thinly serrate, tomentose on both sides; with rudiments of branches from the axils: the spikes heaped, as in the third sort, but oblong, by threes on each peduncle, the middle ones sessile, villous: the flowers are white, appearing in July. It is a native of Sicily.

The third has a biennial, brown root, with many long tough fibres: the stems numerous, woody, branched, a foot and half high: the leaves are downy, entire, pale green, petioled: the flowers small, white, appearing successively between the bracteal leaves, which are numerous, and form roundish compact terminating spikes. It begins to flower in July, when it is cut for use, and called *Knotted Marjoram*, from the flowers being collected into roundish knotted close heads. It is probably a native of China.

The fourth species has a perennial root, from which arise many branching stalks a foot and half high, hairy, and inclining to a purplish colour: the leaves ovate, obtuse, hairy, greatly resembling those of Sweet Marjoram, on short foot-stalks: the flowers in spikes about two inches long, several arising together from the divisions of the stalk: the flowers are small, white, peeping out of their scaly covers. It grows naturally in Greece, &c.

It is at present commonly known by the name of *Winter Sweet Marjoram*, but was formerly called *Pot Marjoram*, being chiefly used for nosegays, as coming sooner to flower than Sweet Marjoram.

There is a variety with variegated leaves.

The fifth is a perennial plant with a low shrubby stalk, seldom rising more than a foot and half high, dividing into branches: the leaves roundish, thick, woolly, hollowed like a ladle; they are like those of common Marjoram, but of a thicker substance, and have much the same scent: the flowers are produced in roundish spikes, closely joined together at the top of the stalks, and at the end of the small side branches; they are of a pale flesh colour, peeping out of their scaly coverings. It is a native of Egypt, flowering from June to August.

The sixth species is also a perennial plant: the stalks hairy, about nine inches high, of a purplish colour, sending out small branches

from the sides by pairs: the leaves round, thick, woolly, very white; the whole plant has a piercing aromatic scent, and biting taste: the flowers are collected in loose leafy heads of a purple colour, nodding, and small. It is a native of the island of Candia, flowering from June to August.

Culture.—The four first sorts may be readily increased by slips, cuttings, and parting the roots, and in the first and third sorts also by seeds.

The seed should be procured fresh from the seed-shops, and be sown in the early spring months, as March or the following month, on a bed or border of good light mould, raking it in lightly. When the plants are up and have attained a few inches in growth, they should be planted out during moist weather, in a warm dry situation, in rows ten or twelve inches distant, to remain, water being given occasionally till they become perfectly rooted. When the plants are designed for the borders or clumps, the seeds may be sown in patches where the plants are to remain.

The roots of the strongest plants may be parted so as to have some root-fibres to each in the early autumn or spring season, and be planted out in rows in the same manner as those raised from seed; having the same management afterwards till fresh rooted. The slips or cuttings of the branches should be taken off in the summer, and immediately planted out where the plants are to remain.

All the sorts should be afterwards kept perfectly clean from weeds during the summer season, and in the autumn have the decayed stalks cleared away, loosening the mould about the plants; and when in beds, digging the alleys and throwing a little of the earth over the beds.

When necessary the plants may be removed into the pleasure ground, with small balls of earth about their roots, either in the autumn or early spring.

The other tender kinds may be increased by planting slips or cuttings of the young shoots, in the spring and summer months; in the former season in pots of light earth, plunging them in a mild hot-bed, but in the latter either in pots or warm shady borders; water being immediately given and occasionally repeated in small proportions, being covered down by hand glasses in the latter case, to expedite their rooting; being removed, when the plants begin to shoot at the top. In the autumn the plants may be removed into separate small pots, and afterwards treated as the more hardy plants of the green-house kind.

The three first sorts are useful as culinary plants, as well as ornamental in the borders of the pleasure ground: and the other kinds afford variety in the green-house collections.

ORNITHOGALUM, a genus containing plants of the bulbous-rooted, flowery, herbaceous, perennial kind.

It belongs to the class and order *Hexandria Monogynia*, and ranks in the natural order of *Coronariæ*.

The characters are: that there is no calyx: the corolla has six petals, lanceolate, upright below the middle, above it spreading, permanent, losing their colour: the stamina have six upright filaments, alternately widening at the base, shorter than the corolla: anthers simple: the pistillum is an angular germ: style awl-shaped, permanent: stigma blunt: the pericarpium is a roundish capsule, angular, three-celled, three-valved: the seeds many and roundish.

The species cultivated are: 1. *O. umbellatum*, Umbelled Star of Bethlehem; 2. *O. luteum*, Yellow Star of Bethlehem; 3. *O. minimum*, Small Star of Bethlehem; 4. *O. Pyrenaicum*, Pyrenean Star of Bethlehem; 5. *O. latifolium*, Broad-leaved Star of Bethlehem; 6. *O. pyramidalis*, Pyramidal Star of Bethlehem; 7. *O. unifolium*, One-leaved Star of Bethlehem; 8. *O. nutans*, Neapolitan Star of Bethlehem; 9. *O. Capense*, Cape Ornithogalum; 10. *O. aureum*, Golden Star of Bethlehem.

The first has a solid bulb, having smaller bulbs joining to it: the root-leaves (sometimes five) soft, keeled, or convex on the outside and channelled within, with a white silvery streak, from one to two lines in width, and above a foot in length, linear, bright green: the scape upright, round, very smooth, a long span or a foot in height, terminating at top in alternate peduncles, very long and broad; all together forming a sort of corymb, resembling an irregular umbel, but not springing from the same point, the lower ones being longer: the flowers are all nearly of the same height; they are one-flowered, and each has a white, membranaceous, lanceolate, very large bracte. Woodward remarks that it is improperly called *umbellatum*, as the flowers are in a most evident spike (or rather corymb). It is a native of the southern parts of Europe, &c., flowering in April and May.

The second species has the root-leaves generally single, and longer than the stem, which is from four to six inches high: the stem-leaves two, three, or four, one very large, the other smaller, all unequal; fringed with fine white hairs: from these arise a few fruit-stalks, (three

to seven) each supporting one flower, and forming an umbel. It is a native of most parts of Europe, flowering in April.

Its roots have been used for food in times of scarcity, in Sweden.

In the third, according to Miller, the bulbs are not larger than peas. There is one or two narrow keel-shaped leaves about five inches long, of a grayish colour, arising from them. The stalk is angular, about four inches high, having two narrow keel-shaped leaves just below the flowers, which are disposed in an umbel on branching peduncles, yellow within but of a purplish green on the outside; they appear in May, and are succeeded by small triangular capsules filled with reddish uneven seeds. It is a native of Sweden, &c.

The fourth species has a naked stem, a foot and half or two feet high: the flowers are in a long spike on slender peduncles, each arising from a membranaceous half-embracing bracte, broad at the base, tapering to a point: the bulb pretty large, with several long keeled leaves coming out from it and spreading on the ground; among these comes out a single naked stalk about two feet long, sustaining a long loose spike of flowers of a yellowish green colour, on pretty long peduncles, and spreading wide from the principal stalk. The flowers have an agreeable scent, and appear in May. It is a native of some parts of Europe.

The fifth has a large bulb; the root-leaves are several, broad, sword-shaped, spreading on the ground: the stalk thick, strong, between two and three feet high, bearing a long spike of large white flowers, upon long pedicels: the leaves are a foot long, and more than two inches in breadth. It has been observed by Clusius, with above one hundred flowers on a spike. It is a native of Egypt and Arabia, flowering in June.

The sixth species has a very large oval bulb, from which arise several long keeled leaves, of a dark green colour; in the middle of these springs up a naked stalk, near three feet high, terminated by a long conical spike of white flowers, on pretty long pedicels. It grows naturally in Spain and Portugal, flowering in June.

The seventh has an ovate bulb, the size of a hazel nut: the leaf is upright, flat, broad-lanceolate, blunt, naked, ciliate, sheathing the scape at the base: the scape upright, round, longer than the leaf, terminated by a few-flowered raceme; the flowers peduncled, alternate. It is a native of the Cape of Good Hope.

The eighth species has a pretty large, com-

pressed bulbous root, from which come out many long, narrow, keeled leaves of a dark green colour. the stalks are very thick and succulent, about a foot high, sustaining ten or twelve flowers in a loose spike, each hanging on a footstalk an inch long. It is a native of Italy, flowering in April and May.

The ninth has an irregular tuberous root, varying greatly in form and size, covered with a dark brown skin, from which spring several leaves, upon pretty long footstalks, having several longitudinal veins: the flower-stalks are slender, naked, and about a foot high, sustaining several small greenish-white flowers, formed in a loose spike, standing upon long slender pedicels: they come out in November. It is a native of the Cape of Good Hope.

The tenth has a whitish bulb, from which spring three or four smooth, somewhat fleshy, upright, dark green leaves, about half an inch wide, and three or four inches long, edged with white, and, if magnified, appearing fringed with very fine villose hairs: the stalk is naked, from eight to twelve inches high, supporting many flowers, which spring from the axils of large, hollow, pointed bractes, and, opening one after another, keep the plant a considerable time in flower; they are usually of a bright orange or gold colour, but sometimes paler. It is a native of the Cape of Good Hope, flowering in January and February.

Culture.—All the sorts are capable of being increased by planting the strong off-sets from the old roots in the latter end of the summer season, when their leaves and stems begin to decay, either in beds or the borders; the old roots may either be immediately replanted or kept out of the ground some time, but they flower much stronger when put into the ground in autumn, than if kept out till the spring. The small off-set bulbs should be planted out in nursery rows in beds for some time, till sufficiently large to be finally set out where they are to grow. They should have a light sandy soil, little manured.

They afterwards require the same management as other hardy bulbs. See BULB; but they should be removed every other year, as when let remain longer they become weak.

The two last sorts should have the off-sets or slips planted in separate pots, at the same time with the above, filled with good light earth, placing them under a hot-bed frame, so as to be protected from wet during the winter season, giving them full air in the summer. The old roots may be taken up in the autumn as in the other sorts, and after being kept a little while out of the ground, be replanted in the beginning of the autumn.

The hardy sorts are all highly ornamental among other flowering bulbous-rooted plants, in the borders, clumps, &c.

And the two last kinds afford variety in the collections of potted plants of the flowering bulbous-rooted sorts.

OROBUS, a genus containing plants of the hardy herbaceous fibrous-rooted perennial flowery kind.

It belongs to the class and order *Diadelphia Decandria*, and ranks in the natural order of *Papilionaceæ* or *Leguminosæ*.

The characters are: that the calyx is a one-leaved perianthium, tubular, blunt at the base: mouth oblique, five-toothed, very short; the three lower toothlets sharper; the two upper shorter, more deeply and bluntly divided: shrivelling: the corolla is papilionaceous: banner obcordate, reflex at the tip and sides, longer: wings two, oblong, almost the length of the banner, rising, with the edges converging: keel manifestly bifid below, acuminate, rising; with the edges converging, parallel, compressed; the bottom ventricose: the stamina have diadelphous filaments, (simple and nine-cleft), ascending: anthers roundish: the pistillum is a cylindrical germ, compressed: style filiform, bent upwards, erect: stigma linear, pubescent on the inner side from the middle to the top: the pericarpium is a round legume, long, acuminate, and ascending at the end, one-celled, two-valved: the seeds very many and roundish.

The species cultivated are: 1. *O. lathyroides*, Upright Bitter-Vetch; 2. *O. luteus*, Yellow Bitter-Vetch; 3. *O. vernus*, Spring Bitter-Vetch; 4. *O. tuberosus*, Tuberous Bitter-Vetch; 5. *O. niger*, Black Bitter-Vetch; 6. *O. Pyrenaicus*, Pyrenean Bitter-Vetch.

The first has a perennial root: the stalks three or four, branching, about a foot high: the leaflets smooth, stiff, of a lucid green: the flowers in close spikes on short peduncles, from the axils of the leaves at the top of the stalks, where are generally three or four of these spikes standing together: the corolla is of a fine blue colour: the flowers appear in June. It is a native of Siberia.

The second species has a very thick root, often transverse, hard, with the fibres widely diffused: the stem is a foot high and more, straight, angular, striated, smooth: the leaflets four or five pairs, entire, veined on both sides, netted, smooth, whitish underneath, terminated by a bristle; sometimes there is an odd leaflet: the stipules semisagittate, entire, or obscurely serrate with distant teeth, of the same colour with the leaves: peduncles angular, striated, smooth, naked, twice as long as the leaves: the flowers in loose spikes,

all directed the same way, twelve or more, of a yellow colour. It is a native of Siberia:

The third has a perennial root, creeping, not tuberous, woody, black, with many strong fibres: the stem about a foot high, upright, unbranched, smooth, angular, twisted or elbowed at each insertion of the leaves: the leaves alternate, petioled, leaflets two or three pairs, without an odd one, large, ovate-lanceolate, sessile, quite entire, nerved, bright green, smooth, tender: the stipules at the base of the petioles large, wide: the flowers are blue. It is a native of many parts of Europe, flowering in March or April.

There are varieties with purple flowers, with pale blue flowers, with deep blue flowers.

The fourth species has a perennial root, consisting of tough fibres, swelling here and there into irregular tubercles, each of which produces a stalk about a foot high, simple, upright, having two or three leafy or winged angles: the leaves are alternate, three or four in number; each consisting of two or three pairs of smooth sessile leaflets without an odd one, the petiole terminated by a kind of awn, as are the leaflets, being a production of the midrib; leaflets all elliptical, blueish underneath, the lower ones broader, the upper approaching to linear, all having three nerves or longitudinal veins: the stipules in pairs at the base of each leaf, frequently entire, but more often jagged at bottom, with one or several teeth: the flowers from two to four or five in a thin spike on naked slender axillary peduncles, of a reddish purple. It is a native of most parts of Europe, flowering in May and June, and sometimes in April.

It is sometimes called *Wood-Pea* and *Heath-Pea*.

The fifth has a perennial root, strong, woody: the stems many, branching, two feet high, having one pinnate leaf at each joint, composed of five or six small, oblong, oval leaflets: the flowers are on very long axillary peduncles, having four, five, or six purple flowers at the top. It is a native of most parts of Europe, flowering from May to July.

The sixth species has the stem angular, with the angles slightly winged, branched, somewhat villose: the leaflets on short petioles; the nerves underneath villose: the stipules oblong, one-tailed: the racemes striated: the flowers directed one way, pendulous: standard obcordate, red, with lines of a deeper colour. It is a native of the South of Europe.

Culture.—All the sorts are capable of being increased by seeds and parting the roots. The seed should be sown in the beginning of the autumn, as in September or October, in the clumps, borders, or other parts where they are to remain,

or on a bed of good earth, to be afterwards pricked out and transplanted. The plants should be kept perfectly free from weeds.

The roots of the large plants may be parted in the autumn, and immediately planted out where the plants are to grow. The small roots may be set in nursery rows, to remain till sufficiently strong for being finally planted out.

They are all hardy flowering ornamental plants for the borders, clumps, and other parts of pleasure-grounds.

ORYZA, a genus containing plants of the exotic annual kind.

It belongs to the class and order *Hexandria Digynia*, and ranks in the natural order of *Gramina* or *Grasses*.

The characters are: that the calyx is a one-flowered glume, two-valved, very small, acuminate, almost equal: the corolla two-valved: valves boat-shaped, concave, compressed, the larger five-angled, awned: nectary (petals of Micheli) two-leaved, flat, on one side of the germ, very small: leaflets narrow at the base, truncate at the tip, caducous: the stamina have six capillary filaments, the length of the corolla: anthers bind at the base: the pistillum is a turbinate germ: styles two, capillary, reflex: stigmas club-shaped, feathered: there is no pericarpium: corolla growing to the seed, oval-oblong, compressed, margins thin, two streaks on each side at the side: the seed single, large, oblong, blunt, compressed, with two streaks on each side.

The species is *O. sativa*, Rice.

It has the culm from one to six feet in length, annual, erect, simple, round, jointed: leaves subulate-linear, reflex, embracing, not fleshy: the flowers in a terminating panicle: the calycine leaflets lanceolate: the valves of the corolla equal in length: the inner valve even, awnless: the outer twice as wide, four-grooved, hispid, awned: the style single, two-parted. It is a native of India.

There are several varieties.

The *Common Rice* has the culm four feet high: the panicle spiked, the spikes commonly simple: the fruit oblong, pale, with long awns. It is late, and is cut from six to eight months after planting.

The *Early Rice* has the culm three feet high: the panicle spiked; spikes branching: the fruit turgid, brownish red, with shorter awns. It ripens and is cut in the fourth month from planting.

The *Dry or Mountain Rice* has the culm three feet high, and more slender: the fruit longish, with awns the longest of all. It is sown on mountains, and in dry soils.

The *Clammy Rice* has the culm four feet high:

the leaves wider, yellowish : panicle large, with shorter awns : the seed oblong, largish, glutinous, usually very white. This is cultivated both in wet and dry places.

It varies with a black seed, which is higher flavoured, and also with a red seed.

There are other varieties.

Culture.—These plants may be increased by seeds in the early spring.

The seeds should be sown on a hot-bed, and when the plants are come up, be transplanted into pots filled with rich light earth, and placed in pans of water, which should be plunged into a hot-bed ; and as the water wastes, it must be renewed from time to time. They must be kept in the stove all the summer, and towards the end of August they will produce the grain, which will ripen tolerably well, provided the autumn prove favourable for the plants.

They afford variety in the hot-house collections.

OSIER. See SALIX.

OSTEOSPERMUM, a genus comprising plants of the shrubby exotic kind for the greenhouse.

It belongs to the class and order *Syngenesia Polygamia Necessaria*, and ranks in the natural order of *Compositæ Discoideæ*.

The characters are : that the calyx is common, simple, hemispherical, many leaflets awl-shaped, small : the corolla is compound, rayed : the corolllets hermaphrodite very many, in the disk : females about ten in the ray : proper of the hermaphrodite tubular, five-toothed, the length of the calyx : of the female ligulate, linear, three-toothed, very long : the stamina in the hermaphrodites have five capillary filaments, very short : anther cylindrical, tubulous : the pistillum in the hermaphrodites has the germ very small : style filiform, scarcely the length of the stamens : stigma obsolete :—in the females, germ globular : style filiform, the length of the stamens : stigma emarginate : there is no pericarpium : calyx unchanged : the seeds in the hermaphrodites none :—in the females solitary, subglobular, coloured, at length hardened, inclosing a kernel of the same shape : pappus none : the receptacle is naked and flat.

The species cultivated are : 1. *O. spinosum*, Prickly Osteospermum ; 2. *O. pisiferum*, Smooth Osteospermum ; 3. *O. moniliferum*, Poplar-Leaved Osteospermum ; 4. *O. polygaloides* ; 5. *O. cæruleum*, Blue-flowered Osteospermum.

The first is a low shrubby plant, which seldom rises above three feet high, and divides into many branches : the ends of the shoots are beset with green branching spines : the leaves are very clammy, especially in warm weather ; they are

long and narrow, and set on without any order : the flowers are produced singly at the ends of the shoots ; they are all yellow, and appear in July and August. It is a native of the Cape of Good Hope, flowering from February to October.

The second species has the angles of the branches toothleted by the back of the petioles running down, and are frequently wholly involved in wool, which disappears with age : the leaves are wedge-form, erose : the peduncles scaly : the flowers small : the seeds obovate : the stem four or five feet high, dividing into many branches towards the top, which spread out flat on every side ; they have a purplish bark. It produces tufts of yellow flowers at the extremity of the shoots, from spring to autumn.

The third rises with a shrubby stalk seven or eight feet high, covered with a smooth gray bark, and dividing into several branches : the leaves alternate, of a thick consistence, covered with a hoary down, which goes off from the older leaves, unequally indented on their edges : the flowers are in clusters at the ends of the branches, six or eight coming out together on petioles an inch and half long, of a yellow colour.

It seldom flowers in this climate ; but the time of its flowering is July or August.

The fourth species has three small branches : the leaves small, oblong, sessile, on some of the upper branches imbricate : the flowers come out at the end of the branches, standing singly on peduncles about an inch long.

The fifth is an undershrub, three feet high, with a strong smell : the root woody, branching, fibrous : the stem somewhat woody, erect, round, regularly branched, gray : the leaves alternate, spreading : segments alternate, (some almost opposite,) oblong, acute, serrate ; the lower sinuses wider, deeper, parallel to the midrib ; the upper ones rounded ; they are without veins, and have only one nerve prominent beneath ; are of the same colour on both sides, and fragrant, from an inch and a half to two inches in length, and fifteen lines in breadth : the flowers terminating, very loosely corymbed, peduncled, erect, blue, an inch wide. It is a native of the Cape.

Culture.—These plants may be increased by cuttings of the young shoots, which may be planted in any of the summer months, upon a bed of light earth, being watered and shaded until they have taken root, when they must be taken up and planted out separately in pots ; as when they are suffered to stand long, they are apt to make strong vigorous shoots, and be difficult to transplant afterward, especially the second and third sorts ; but there is not so much danger of the first, which is not so vigorous, nor so easy in taking root as the other. In the summer season

the pots should be frequently removed, to prevent the plants from rooting through the holes in the bottoms of the pots into the ground, which they are very apt to do when they continue long undisturbed, and when they shoot very luxuriantly; and on their being removed, these shoots, and sometimes the whole plants, are destroyed.

As the plants are too tender to live in the open air in this climate, they should be placed in the green-house in October, and be treated in the same manner as Myrtles, and other hardy green-house plants, which require a large share of air in mild weather; and in the beginning of May the plants removed into the open air, and placed in a sheltered situation during the summer season. As the first and second sorts are very thirsty plants, they should have plenty of water.

These plants afford variety among others of the green-house kind.

OSWEGO TEA. See MONARDA.

OSYRIS, a genus containing a plant of the shrubby kind.

It belongs to the class and order *Dioecia Triandria*, and ranks in the natural order of *Calycifloræ*.

The characters are: that in the male, the calyx is a one-leafed perianthium, trisid, turbinate: segments equal, ovate, acute: there is no corolla, except a triple nectariferous rim: the stamina have three filaments, very short: anthers roundish, small: in the female, the calyx is a perianthium as in the male, superior, permanent, very small: there is no corolla, as in the male: the pistillum is a turbinate germ, inferior: style the length of the stamens: stigma three-parted, spreading, (roundish): the pericarpium is a globular berry, one-celled, umbilicated: the seeds bony, globular, filling the pericarpium.

The species cultivated is *O. alba*, Poet's Casia.

It is a very low shrub, seldom rising above two feet high, having woody branches: the leaves long, narrow, of a bright colour: the flowers of a yellowish colour; succeeded by berries, which at first are green, and afterwards turn to a bright red colour, like those of the Asparagus. It is a native of France, &c.

Culture.—These plants are increased, by sowing the berries in autumn as soon as ripe, in some gravelly, stony, or similar situation, on the side of a rising ground, either in the places where the plants are to remain, which is the most successful, or in a nursery-bed for transplanting. As the seeds often remain two years before they vegetate, the places should be kept clear from weeds during that time, or till the plants appear. They afterwards require only to be freed from weeds.

They afford variety in beds, borders, or other places, by the beauty of their fruit.

OTHONNA, a genus containing plants of the shrubby exotic evergreen kind.

It belongs to the class and order *Syngenesia Polygamia Necessaria*, and ranks in the natural order of *Compositæ Discoideæ*.

The characters are: that the calyx is common, quite simple, one-leafed, blunt at the base, sharp at the end, equal, divided into eight or twelve segments: the corolla compound, rayed: corollets hermaphrodite many, in the disk: females in the ray, the same number with the segments of the calyx, often eight (about ten): proper of the hermaphrodite, tubular, five-toothed, scarcely longer than the calyx: of the female, ligulate, lanceolate, longer than the calyx, three-toothed, reflex: the stamina in the hermaphrodites, filaments five, capillary very short: anther cylindric, tubular, the length of the corollet: the pistillum in the hermaphrodites, germ oblong: style filiform, commonly longer than the stamens: stigma bifid, simple: in the females, germ oblong: style filiform, the same length as in the others: stigma reflex, larger: there is no pericarpium: calyx unchanged, permanent: the seeds in the hermaphrodites none: in the females solitary, oblong, naked or downy: the receptacle is naked, dotted: (somewhat villose in the middle, excavated about the edge.)

The species cultivated are: 1. *O. bulbosa*, Bulbous African Ragwort; 2. *O. pectinata*, Wormwood-leaved African Ragwort; 3. *O. abrotanifolia*, Southernwood-leaved African Ragwort; 4. *O. coronopifolia*, Buckshorn-leaved African Ragwort; 5. *O. cheirifolia*, Stock-leaved African Ragwort; 6. *O. arborescens*, Tree African Ragwort.

The first has a thick shrubby stalk, dividing into several branches, which rise five or six feet high; the leaves come out in clusters from one point, spread on every side; they are smooth, narrow at their base, enlarging gradually to their points, which are rounded; their edges are acutely indented like those of the Holly: from the centre of the leaves arise the foot-stalks of the flowers, which are five or six inches long, branching out into several smaller, each sustaining one yellow radiated flower, shaped like the former; these are succeeded by slender seeds crowned with down. It flowers in May and June.

It is herbaceous, and varies with ovate, quite entire leaves; with the root-leaves pinnate, quite entire; with the leaves linear, very narrow; with the leaves lanceolate, quite entire; with the leaves lanceolate, toothed; with the leaves lanceolate-sub-elliptic; with the leaves

sublanceolate, three-toothed, or shrubby; with the leaves of the top lanceolate, subsessile; and with the leaves alternate, lanceolate, toothed. It is an extremely variable plant.

The second species rises with a shrubby stalk about the thickness of a man's thumb, two or three feet high, dividing into many branches, covered with a hoary down: the leaves hoary, about three inches long and one broad, cut into many narrow segments almost to the midrib; these segments are equal and parallel, and have two or three teeth at the end: the flowers are produced on long axillary peduncles towards the ends of the branches; they have large yellow rays; and are succeeded by oblong purple seeds crowned with down. It flowers in May and June.

The third has a low, shrubby, branching stalk: the leaves are thick, like those of Sampire, and are cut into many narrow segments: the flowers are produced on short peduncles at the ends of the branches, are yellow, and the seeds brown. It flowers from January to March.

The fourth species rises with a shrubby stalk four or five feet high, dividing into several branches: the leaves grayish, placed without order; those on the lower part narrow and entire, but the others indented on the edges: the flowers are produced in loose umbels at the ends of the branches, and are yellow. It flowers from July to September.

The fifth has a strong fibrous root, which shoots deep in the ground, and sends out many woody stems, which spread on every side, and trail upon the ground: the leaves grayish, sessile, and of a thick consistence, narrow at the base, enlarging upwards, and broad at their points, where they are rounded: the flowers are produced upon long, thick, succulent, peduncles at the ends of the branches, and from the axils; they are yellow, the rays sharp jointed, and not much longer than the calyx, which is cut into eight equal segments at top; the disk is large, and the florets as long as the calyx. It is a native of Africa.

The sixth species has the height (at five years of age) of one foot, with a stem the thickness of a human finger, resembling *Sedum arborescens*, and like that fleshy and woody, though never so tall or thick, pliant, covered with a brownish ash-coloured bark, not rough but rather smooth, and having woolly tubercles scattered over it: the branches also have them, and are obliquely curved inwards: the ends of the branches and base of the leaves have a fine wool on them, not conglobated but scattered: the branches are otherwise naked, somewhat woody, covered

with a bark like that of the stem, brownish green towards the end, more tender and herbaceous; these leaves come out alternately at short distances; they are oblong, wider towards the top, and blunt; contracted towards the base, green on both sides, somewhat glittering, and as it were mealy, like those of *Auricula*, flat, thickish, succulent and smooth, veinless, with only a white nerve protuberant underneath, and on the upper part a little hollowed next the base. It is a plant that makes very slow progress in this climate. In August it puts out young leaves, which it keeps all the winter; the heads of flowers appear about the end of November, and do not open till the middle or end of January: in spring the leaves gradually drop off, and the plant appears as if dead till the succeeding autumn.

All the species, except the fifth, are natives of the Cape.

Culture.—These plants may be increased, by planting slips and cuttings of the young shoots or branches during the summer months, in pots filled with fine earth, plunging them in an old tan hot-bed under glasses, carefully shading them from the heat of the sun till perfectly rooted; their striking may be promoted by being covered with small glasses. When they are become well rooted, they should be removed with balls into separate pots filled with loamy mould, placing them in a sheltered shady situation till autumn.

They should be preserved in a good greenhouse in the winter, having as much free air as possible, and in the summer placed in a sheltered warm situation.

The fifth sort may sometimes be preserved in the open ground in such situations.

They produce variety among other potted plants of the green-house kinds.

OXALIS, a genus containing plants of the hardy herbaceous perennial kind.

It belongs to the class and order *Decandria Pentagynia*, and ranks in the natural order of *Gruinales*.

The characters are: that the calyx is a five-parted perianthium, acute, very short, permanent: the corolla five-parted, often coloring by the claws, erect, obtuse, emarginate: border spreading: the stamina have ten capillary filaments, (awl-shaped,) erect; the outer ones shorter: anthers roundish, grooved: the pistillum is a five-cornered germ, superior: styles five, filiform, the length of the stamens: stigmas blunt: the pericarpium is a capsule, five-cornered, five-celled, ten-valved, (Jacqu.) five-valved gaping at the corners longitudinally: the seeds are roundish, flying out covered with a fleshy elastic aril.

The species cultivated are : 1. *O. Acetosella*, Common Wood Sorrel; 2. *O. stricta*, Upright Wood Sorrel; 3. *O. caprina*, Goat's-foot Wood Sorrel; 4. *O. versicolor*, Striped-flowered Wood Sorrel; 5. *O. purpurea*, Purple Wood Sorrel; 6. *O. incarnata*, Flesh-coloured Wood Sorrel.

There are many other species that may be cultivated.

The first has a perennial root, branched, round, knobbed, creeping, with very fine fibrils on every side, partly white, partly red, having an ovate, acute, thick, rigid scale like a tooth at the knobs: stipe partly subterraneous, partly standing out; sometimes very little, sometimes several inches, then procumbent and striking roots into the ground, toothleted at the knobs like the root, round, somewhat hirsute, red, closely toothleted above with the permanent joints of decayed leaves, perennial, putting forth from its top several aggregate leaves and scapes: the petiole jointed, round, somewhat hirsute, red, especially at bottom, from two to three inches long, almost upright but weak: the leaflets subsessile, near half an inch long, wider, green and hirsute on both sides, shortly ciliate: the scapes one or two, jointed at the base, round, somewhat villose, red, the length of the leaves; with embracing, villose, jointed bractes above the middle: the calycine leaflets oblong, acute, sometimes bifid, somewhat hirsute, ciliate, purple at the tip, upright. It is a native of Europe.

There is a variety with purple flowers.

The second species has a perennial, creeping root, round, putting out capillary fibres at the knobs, branched: the stems from the root as it creeps along several, roundish, slender, somewhat villose, purplish, finally branched, half a foot high and more, upright, but being weak often lying down, annual: the leaves are alternate, a few sometimes opposite, ternate: the petiole springing from a joint margined in front, round, villose, spreading, from two to four inches long, flaccid: the leaflets subpetioled, somewhat hirsute on both sides with decumbent hairs and green, ciliate, scarcely half an inch long: the peduncles axillary, jointed at the base, round, villose, upright, about the same length with the leaves, having from two to seven flowers in an umbel, with a pedicel often branched. It is a native of North America, flowering from June to October.

The third has the bulb ovate-triangular, even: the stipe subterraneous, terminated by an umbel of leaves and scapes: leaves several: the petiole jointed at the base, channelled, smooth, from two to three inches in length: leaflets obcordate, sessile, green above, bright purple underneath, a third part of an inch in length; lobes oblong,

VOL. II.

rounded; the scapes several, smooth, erect, slender, half a foot in length, umbelliferous: the leaflets of the involucre few, acute, minute, smooth: peduncles from two to four, one-flowered, sometimes villose, erect, about an inch in length: the flowers of a yellow colour. It is a native of the Cape.

The fourth species has an ovate bulb, half an inch long, covered with a black skin, within which are frequently several bulbs: hence when cultivated it has almost always many stipes: these are out of the ground, have a few scales on them, are round, slender, have a very few hairs scattered over them, are six inches long, sometimes leafless, sometimes having a single leaf at top, when young almost upright, but afterwards wholly procumbent, terminated by a dense umbel of leaves and flowers: leaves several, upright, and spreading a little: petiole jointed at the base, filiform, villose, from one to two inches in length: leaflets subsessile, wedge-form-linear, emarginate, at the edges and underneath appearing somewhat villose when magnified, above smooth and dotted, underneath having two orange-coloured calluses below the tip, about half an inch in length: the scapes several, jointed at the base, round, a little hirsute at top with capitate hairs, in other parts with simple ones, almost upright, longer than the petioles and twice as thick; bractes alternate, approximating, and ciliated at top with capitate hairs: calycine leaflets lanceolate, acute, erect, ciliate and hirsute with capitate or simple hairs, green with the edges blood-red, and two oblong orange-coloured calluses below the tip connected at top. It is a native of the Cape.

The fifth has also an ovate bulb, loose, small, loosely inclosed in a skin, from three to six times the size of the bulb: the stipe subterraneous, from one to three inches long, round, slender, often bulbiferous, terminated by a dense umbel of leaves and flowers: the leaves very many, spreading or lying on the ground: the petiole jointed at the base, densely villose, pale green, from one to three inches long: the leaflets sessile, quite entire, villose at the edges, quite smooth above, underneath somewhat hirsute and much dotted, always green on both sides without any other colour, half an inch and more in length: scapes several, jointed at the base, round, somewhat villose, pale green, almost upright, longer than the leaves: bractes sublinear, sharp, villose, approximately alternate at bottom: the calycine leaflets lanceolate, acute, hirsute, ciliate, with simple hairs, green with blood-red spots at the edges, erect. It is a native of the Cape.

The sixth species has the bulb in the young plant ovate, covered with a brown skin, twice

2 A

the size of a pea: the root in the mature plant consists of several legs slenderly fusiform, terminating in a long fibre, round, the thickness of a reed and more, some inches in length, fleshy, brittle, pale, somewhat pellucid and sweet: the stipes very many, herbaceous, round, the thickness of a pigeon's quill, or even of a reed, thick, green or purplish brown, a foot and a half high, upright, but so weak as not to be able to support themselves without assistance, at the base and origin of the branches having an ovate-acuminate stipule; both they and the branches terminated by distant umbels of leaves and flowers: the leaves several, at remote distances in whorls: the petiole jointed at the base, round, slender, smoothish, spreading a little, about two inches in length, green: the leaflets on short petioles, equal, quite entire, flat, spreading very much, about half an inch in length, above green and smooth, underneath dotted, more or less purple-flesh-coloured, appearing densely villose in the magnifier, with a row of orange-dots, becoming black in the dried leaves, and observable only in the microscope with the light thrown on it: the peduncles jointed at the base, axillary,

round, pubescent in the magnifier, green, the length of the leaves; with bractes towards the top opposite, erect and jointed: above these nodding and purple.

Culture.—The first sort may be readily increased, by planting the divided roots in a moist shady border in the early spring season; and afterwards they require only to be kept clear from weeds.

The other sorts may be increased, by planting off-sets from the roots or bulbs that come out from the sides of the stems, in pots filled with good light mould, sheltering them in the dry stove or under a frame during the winter, admitting as much free air as possible in mild weather. They only require to be protected in the winter season afterwards, and occasionally removed into other pots.

The two first sorts and varieties may be introduced in the borders, and the others afford variety among other potted plants.

P Æ O

PÆONIA, a genus comprising plants of the large herbaceous flowery perennial kind.

It belongs to the class and order *Polyandria Digynia*, and ranks in the natural order of *Multisiliquæ*.

The characters are: that the calyx is a five-leaved perianthium, small, permanent: leaflets roundish, concave, reflex, unequal in size and situation: the corolla has five roundish petals, concave, narrower at the base, spreading, very large: the stamina have numerous filaments, (about three hundred) capillary, short: anthers oblong, quadrangular, erect, four-celled, large: the pistillum consists of two ovate germs, erect, tomentose: styles none: stigmas compressed, oblong, blunt, coloured: the pericarpium has as many capsules, ovate-oblong, spreading and reflex, tomentose, one-celled, one-valved, opening longitudinally inwards: the seeds several, oval, shining, coloured, fastened to the opening suture.

P Æ O

The species are: 1. *P. officinalis*, Common Peony; 2. *P. tenuifolia*, Slender-leaved Peony.

The first has a thick large root, constituted of several thick fleshy tubers, hanging by strings to the main head, with upright round smooth stems, branching half a yard or two feet in height: the leaves are large, many-lobed, with oblong-oval spreading folioles: the flowers large, deep red or purple, on the terminations of the stalks.

There are two principal varieties: the Common Female and Male Peony.

The former of these has the roots composed of several roundish thick knobs or tubers, which hang below each other, fastened with strings: the stalks are green, about two feet and a half high: the leaves composed of several unequal lobes, which are variously cut into many segments: they are of a paler green than those of the latter sort, and hairy on their under side: the flowers are smaller, and of a deeper purple colour.

✓ The latter has the roots composed of several oblong knobs hanging by strings fastened to the main head: the stems the same height with the preceding: the leaves are composed of several ovate lobes, some of which are cut into two or three segments; they are of a lucid green on their upper side, but are hoary on their under: the stems are terminated by large single flowers, composed of five or six large roundish red petals.

The flowers in both sorts appear in May, and are natives of several parts of Europe, as Switzerland, Dauphiné, Carniola, Piedmont, Silesia, &c.

Miller says, that "it is scarcely necessary to observe that the old names of Male and Female have nothing to do here with the sexes, the flowers of both being hermaphrodite."

There are several subvarieties of the *Female Peony* with double flowers, differing in size and colour, cultivated in gardens. The *Male Peony* also varies with pale, and white flowers, and with larger lobes to the leaves: they also vary much in different countries.

"There is the *Foreign Peony*, with a deep-red flower: the roots are composed of roundish knobs, like those of the *Female Peony*: the leaves are also the same, but of a thicker substance: the stalks do not rise so high: the flowers have a greater number of petals, and appear a little later. It is a native of the Levant. The large double purple Peony is probably a subvariety of this."

The *Hairy Peony*, with a larger double red flower: the roots like the common *Female Peony*; but the stalks taller, and of a purplish colour: the leaves much longer, with spear-shaped entire lobes: the flowers large, and of a deep red colour.

The *Tartarian*, with roots composed of oblong fleshy tubers of a pale colour: the stalks about two feet high, pale green: the leaves composed of several lobes, irregular in shape and size, some having six, others eight or ten spear-shaped lobes, some cut into two or three segments, and others entire; of a pale green, and downy on their under side: the stalks are terminated by one flower of a bright-red colour, a little less than that of the common *Female Peony*, having fewer petals.

The *Portugal Peony*, with a single sweet flower, has not roots composed of roundish tubers, but has two or three long taper forked fangs like fingers: the stalk rises little more than a foot high: the leaves are composed of three or four oval lobes, of a pale colour on their upper side, and hoary underneath: the stalk is terminated by a single flower, which is of a bright red co-

lour, smaller than the above, and of an agreeable sweet scent.

The second species has a creeping root, putting forth tuberosus fibres, with tubercles the size of a hazel nut, white, fleshy, of a bitterish taste: the stem scarcely a foot high, and commonly single, but in the garden eighteen inches high, and several from the same root: the root-leaves none: the stem round, very obscurely grooved, smooth, as is the whole plant, naked at bottom, having there only a few sheathing scales: the leaves frequent, alternate, the upper ones gradually less, on a round petiole, channelled above, quinate: the leaflets cut into very many narrow segments: the upper leaves simply multifid: the flower sessile at the uppermost leaf, subglobose, accompanied by two leaflets, one multifid, the other simple, both dilated at the base. It is a native of the Ukraine.

Culture.—The single sorts are easily raised by seed, and the double by parting the roots.

The seed should be sown in autumn, soon after it is perfectly ripened, or very early in the spring, (but the former is the better season,) on a bed or border in the open ground where the soil is rather light, raking it in lightly. It may also be sown in small drills.

The plants should afterwards be properly thinned, kept perfectly free from weeds, and be occasionally watered when the weather is hot and dry.

As they should remain two seasons in the beds, it is necessary in the second autumn to spread some light mould over them, to the depth of an inch; and in the autumn following they may be removed where they are to remain. Plants of the double-flowered kinds are often produced from these.

The roots of the old double-flowered plants may be taken up in the beginning of the autumn, and divided so as to have one bud or eye or more to each part, or crown, as without care in this respect they never form good plants. And where regard is had to the flowering, they should not be too much divided, or the off-sets made too small, as when that is the case they do not flower strong. But where a great increase is wanted, they may be divided more, being left longer in the nursery-beds.

They should be planted out as soon as possible after they are separated, though when necessary they may be kept some time out of the earth. The large off-sets may be set out at once where they are to remain; but the small ones are best set in nursery-beds for a year, or till of proper strength for planting out.

The plants may afterwards be suffered to remain several years unremoved, till the roots are increased to very large bunches, and then be

taken up, when the stalks decay, in autumn, divided, and replanted in their allotted places in the manner directed above.

All the sorts are hardy plants, that are capable of flourishing in any common soil in almost any situation, either in open exposures or under the shade of trees.

The Portugal variety, however, should have a warmer situation and lighter soil than the others.

They are proper ornamental flowery plants for large borders, and may be had at all the public nurseries. In planting, one should be put here and there in different parts, placing them with the crowns of the roots a little within the surface of the earth, and at a yard at least distant from other plants, as they extend themselves widely every way, assuming a large bushy growth; and, together with their conspicuous large flowers, exhibit a fine appearance, and are often planted at the terminating corners of large borders adjoining principal walls, displaying a bushy growth in their foliage and flowers. When the flowers are gone, the capsules opening lengthways discover their coloured seeds very ornamentally, especially in that called the Male Peony and varieties. And to forward this, the capsules may be slit open on the inside at the proper valve; whereby they will expand much sooner, and display their beautiful red seed more conspicuously.

PALM TREE. See **CHAMÆROPS** and **COCOS**.

PALMA CHRISTI. See **RICINUS**.

PALMETTO. See **CHAMÆROPS**.

PANAX, a genus containing plants of the herbaceous and shrubby perennial kinds.

It belongs to the class and order *Polygamia Dioecia* (*Pentandria Digynia*), and ranks in the natural order of *Hederaceæ*.

The characters are: that in the hermaphrodite flowers the calyx is a simple umbel, equal, clustered; involucre many-leaved, awl-shaped, small, permanent; perianthium proper, very small, five-toothed, permanent; the corolla universal uniform; proper, of five oblong equal recurved petals; the stamina have five filaments, very short, caducous; anthers simple; pistillum a roundish germ, inferior; styles two, small, upright; stigmas simple; the pericarpium is a cordate berry, umbilicate, two-celled: the seeds solitary, cordate, acute, plano-convex: male flowers on a distinct plant: the calyx is a simple umbel, globular; with very many equal coloured rays: involucre composed of lanceolate sessile leaflets, the same number with the external rays; perianthium turbinate, quite entire, coloured: the corolla has five petals, oblong, blunt, narrow, reflex, placed on the perianthium: the stamina have five filaments, filiform, longer, inserted into the perianthium: anthers simple.

1

The species cultivated are: 1. *P. quinquefolia*, Ginseng; 2. *P. trifolia*, Three-leaved Panax; 3. *P. aculeata*, Prickly Panax.

The first has a fleshy taper root as large as a man's finger, jointed, and frequently divided into two branches, sending off many short slender fibres: the stalk rises near a foot and half in height, and is naked at the top, where it generally divides into three smaller foot-stalks, each sustaining a leaf composed of five spear-shaped leaflets, serrate, pale green and a little hairy: the stalk is erect, smooth, round, simple, tinged of a deep purple colour: the leaves arise with the flower-stem from a thick joint at the extremity of the stalk; are generally three, but sometimes more: the five leaves into which each of these is divided are of an irregular oval shape, veined, pointed, smooth, deep green above, on short foot-stalks, from a common petiole, which is long, round, and almost erect: the flowers grow on a slender peduncle, just at the divisions of the petioles, and are formed into a small umbel at the top; they are of an herbaceous yellow colour, and appear at the beginning of June: the berries are first green, but afterwards turn red; and inclose two hard seeds, which ripen in the beginning of August, or soon afterwards. It is a native of Chinese Tartary.

The second species has the stem single, not more than five inches high, dividing into three foot-stalks, each sustaining a trifoliate leaf, with the leaflets longer, narrower, and more deeply indented on their edges than in the first species: the flower-stalk rises, as in that, from the divisions of the petiole. It is a native of North America.

It is so nearly allied to the first sort, that Linnaeus doubts whether it be any thing more than a variety of that, only much smaller.

The third is a shrub with a recurved prickly at the base and at the tip of the petioles: the leaves are solitary, ternate, tern at the flowers; with ovate, blunt leaflets: the umbels are peduncled, hemispherical, and simple: the flowers with three styles. It is a native of China.

Culture.—The first and second sorts are increased by sowing the seeds procured from abroad upon a moderate hot-bed, or in pots plunged into it, in the early spring season; and when the plants have acquired a few inches in growth, removing them into beds or borders where the mould is good, and the situations sheltered.

The third sort is increased by layers or cuttings, laid down or planted out in the summer months in pots, and plunged in the bark-bed of the stove. When they have stricken root, they may be removed into separate pots, and be constantly kept in the stove.

Painted by Syd Edwards

London Published June 1 1873. by G. Kearsley Fleet Street

Engraved by F. Nankin

Pancratium maritimum.
See *Pancratium*

Soldanella alpina
² *Alpine Soldanella*

The two first sorts afford variety in the borders, and the last among stove collections.

PANCRATIUM, a genus containing plants of the bulbous-rooted flowery perennial kind.

It belongs to the class and order *Hexandria Monogynia*, and ranks in the natural order of *Spathaceæ*.

The characters are: that the calyx is an oblong spathe, obtuse, compressed, opening on the flat side, shrivelling: the corolla has six petals, lanceolate, flat, inserted into the tube of the nectary on the outside above the base: nectary one-leaved, cylindric-funnel-form, coloured at top, with the mouth spreading and twelve-cleft: the stamina have six filaments, awl-shaped, inserted into the tips of the nectary, and longer than they are: anthers oblong, incumbent: the pistillum is a bluntly three-cornered germ, inserted into the filaments, longer than the stamina: style short: the pericarpium is a roundish capsule, three-sided, three-celled, three-valved: the seeds several, globular.

The species cultivated are: 1. *P. maritimum*, Sea Pancratium; 2. *P. Illyricum*, Illyrian Pancratium; 3. *P. Zeylanicum*, Ceylon Pancratium; 4. *P. Mexicanum*, Mexican Pancratium; 5. *P. Caribæum*, Caribbean Pancratium; 6. *P. Carolinianum*, Carolina Pancratium; 7. *P. Amboinense*, Broad-leaved Pancratium; 8. *P. verecundum*, Narcissus-leaved Pancratium.

The first has a large, coated, bulbous root, of an oblong form, covered with a dark skin: the leaves are shaped like a tongue; are more than a foot long, and one inch broad, of a deep green, six or seven of them rising together from the same root, encompassed at bottom with a sheath: between these arises the stalk, which is a foot and half long, naked, sustaining at the top six or eight white flowers, inclosed in a sheath, which withers and opens on the side, to make way for the flowers to come out.

According to Mr. Miller, the root resembles that of the Squill, but is less, covered with a brown skin, and white within, the coats pellucid and gently striped, viscid or full of a clammy juice, bitter to the taste without acrimony. It is a native of the South of Europe.

The second species has a large bulb, covered with a dark skin, sending out many thick strong fibres, striking deep in the ground: the leaves are a foot and half long and two inches broad, of a grayish colour: the scapes thick, succulent, near two feet high: the flowers six or seven, white, shaped like those of the first sort, but with a shorter tube, and much longer stamina. It flowers in June, and frequently produces seeds. It is a native of the South of Europe.

The third has a pretty large bulbous root: the

leaves long and narrow, of a grayish colour, and pretty thick, standing upright: the stalk rises among them, a foot and half high, naked, sustaining one flower at the top: the nectary is large, cut at the brim into many acute segments: the stamina long, and turning towards each other at their points; in which it differs from the other species: the flower has a very agreeable scent, but is of short duration. It is a native of Ceylon.

The fourth species has the stem or scape a long span in height, round, forked towards the top, or dividing into two peduncles, with two oblong tender membranaceous greenish leaflets, and terminated each with a white flower, divided to the very base into six narrow segments; in the middle of these is a white bell-shaped tube, which Linnæus names the nectary, more tender than the petals; the mouth angular, and from each angle putting forth a filament, long, slender and white, terminated by an oblong incurved saffron-coloured anther: the flowers have no smell, and shrivel up over the fruit: leaves four, reclining, smooth, pale green and somewhat glaucous, ridged, slightly grooved in the middle, and with a single streak on each side, otherwise veinless, a long span or a little more in length, an inch or an inch and half in width, produced to a point at the end. It flowers in May.

The fifth has the leaves about a foot long and two inches broad, having three longitudinal furrows: the stalk rises about a foot high, then divides like a fork into two small foot-stalks, or rather tubes, which are narrow, green, and at first encompassed by a thin spathe, which withers, and opens to give way to the flowers: these are white, and have no scent. It is a native of the West Indies.

The sixth species has a roundish bulbous root, covered with a light brown skin, from which arise several narrow dark green leaves, about a foot long: among these comes out a thick stalk (scape) about nine inches high, sustaining six or seven white flowers, with very narrow petals, having large bell-shaped nectariums or cups, deeply indented on their brims: the stamina do not rise far above the nectarium. It is a native of Jamaica and Carolina.

The seventh has the bulb oblong, white, sending out several thick fleshy fibres, which strike downward: the leaves are on very long foot-stalks, some ovate, others heart-shaped, about seven inches long and five broad, ending in points, having many deep longitudinal furrows; they are of a light green, and their borders turn inwards: the stalk thick, round, and succulent, rising near two feet high, sustaining at the top several white flowers, shaped like those of:

the other sorts; but the petals are broader, the tube is shorter, and the stamens are not so long as the petals: there is a thin sheath, which splits open longitudinally. It is a native of Amboyna.

There are several varieties: as the *American*, which grows naturally in the islands of the West Indies, where it is called *White Lily*; and the *latifolium* and *ovatum* also grow naturally in the same place.

The eighth species has the leaves a foot and a half long, half an inch wide: the scape erect, compressed, a foot high: the spathes oblong-lanceolate, acuminate, whitish, shrivelling; the outer larger, an inch and half in length: the flowers fragrant, on three-cornered pedicels, scarcely half an inch long. It is a native of the East Indies; flowering from June to August.

Culture.—All these plants are capable of being increased by planting off-sets from the roots in the latter end of summer, when their stems and leaves decay. The roots may be divided every second or third year.

In the two first sorts, the off-sets may be planted out in nursery-beds for a year or two, to become sufficiently strong, when they may be removed into warm sheltered dry borders; the first being sheltered from frost in severe winters, and the latter in very severe weather, by being covered with tanner's bark, straw, or peas-haulm. The second sort may also be increased by seeds sown in pots, and plunged in a hot-bed.

The other sorts must be planted out in small pots filled with light earth, separately plunging them in the bark-bed of the stove. They should be kept constantly in the tan-bed, and have the management of other tender bulbs. In this way they generally succeed well.

The two first sorts afford variety in the dry warm borders of the pleasure-ground, and the other kinds produce variety as well as fragrance in the stove collections.

PANDANUS, a genus containing a plant of the herbaceous perennial exotic kind, for the stove.

It belongs to the class and order *Dioecia Monandria*.

The characters are: that in the male the calyx has alternate spathes, sessile, serrate-pointy: spadix decomposed, naked: perianthium proper none: corolla none: the stamens have very many filaments, solitary, placed scatteredly on the outer ramifications of the spadix, very short: anthers oblong, acute, erect: in the female, the calyx has four spathes, terminating, converging: spadix globular, covered with numerous fructifications, scarcely included: perianthium none: there is no corolla: the pistillum has numerous aggregate

germs, sessile, five-cornered, convex at top, smooth: style none: stigmas two, cordate, margined: the pericarpium a sub-globular fruit, large, consisting of numerous wedge-shaped drupes, convex at top, angular, farinaceous, one-seeded: the seed solitary, oval, even, in the centre of the drupe.

The species is *P. odoratissimus*, Sweet-scented Pandanus, or Screw Pine.

This is sometimes found with a single and pretty erect trunk of ten feet in height, and a branching round head; but is generally in form of a very large, branching, spreading bush. From the stems or larger branches issue large carrot-shaped blunt roots, descending till they come to the ground, and then dividing: the substance of the most solid is something like that of a cabbage stalk, and by age acquires a woody hardness on the outside: the leaves are confluent, stem-clasping, closely imbricated in three spiral rows, round the extremities of the branches, bowing from three to five feet long, tapering to a very long fine triangular point, very smooth and glossy; margins and back armed with very fine sharp spines; those on the margins point forward; those of the back point sometimes one way, sometimes the other.

The male flowers are in a large, pendulous, compound, leafy raceme, the leaves of which are white, linear-oblong, pointed and concave.

The female flowers are on a different plant, terminating and solitary, having no other calyx or corolla than the termination of the three rows of leaves forming three imbricated fascicles of white floral leaves, like those of the male raceme, which stand at equal distances round the base of the young fruit. It is a native of the warmer parts of Asia, flowering chiefly during the rainy season; it is much employed there for hedges, and answers well, but takes much room. The tender white leaves of the flowers, chiefly those of the male, yield that most delightful fragrance for which they are so generally esteemed; and of all the perfumes, it is by far the richest and most powerful.

Culture.—This plant may be increased by sowing the seeds, brought from the places where it grows naturally, in pots of light earth, and plunging them in the bark-bed of the stove, where they must be constantly retained, having the management usually practised for other tender exotic plants.

They have a fine ornamental effect among other stove plants, in their large spreading foliage.

PAPAVER, a genus containing plants of the hardy herbaceous fibrous-rooted annual and perennial kinds,

Painted by Ed Edwards

London Published Feb 1 1860 by G Kearsley Fleet Street

Engraved by F Sanford

1 *Papaver Orientale*
Eastern Poppy

2 *Pulmonaria virginica*
Virginia Lung-wort

It belongs to the class and order *Polyandria Monogynia*, and ranks in the natural order of *Rhodalece*.

The characters are: that the calyx is a two-leaved perianthium, ovate, emarginate: leaflets subovate, concave, obtuse, caducous: the corolla has four roundish petals, flat, spreading, large, narrower at the base; alternately less: the stamina have numerous filaments, capillary, much shorter than the corolla: anthers oblong, compressed, erect, obtuse: the pistillum has a roundish, large germ: style none: stigma peltate, flat, radiate: the pericarpium is a crowned capsule, with the large stigma, one-celled, half-many-celled, opening by many holes at the top under the crown: the seeds numerous, very small: receptacles, longitudinal plait, the same number with the rays of the stigma, fastened to the wall of the pericarpium.

The species cultivated are: 1. *P. somniferum*, White Poppy; 2. *P. Rhoeas*, Corn or Red Poppy; 3. *P. Cambricum*, Welsh Poppy; 4. *P. Orientale*, Oriental Poppy.

The first has the stalks large, smooth, five or six feet high, branching: the leaves large, grayish, embracing at the base, irregularly jagged on their sides: the flowers terminating, whilst inclosed in the calyx hanging down, but before the corolla expands becoming erect: the calyx is composed of two large oval grayish leaves, that separate and soon drop off: the corolla is composed of four large, roundish, white petals, of short duration; and succeeded by large roundish heads as big as Oranges, flattened at top and bottom, and having an indented crown or stigma: the seeds are white. It is a native of the southern parts of Europe, but probably originally from Asia.

There are several varieties, differing in the colour and multiplicity of their petals, which are preserved in gardens for ornament: the Single-flowered sort is chiefly cultivated for use.

The Common Black variety of Poppy has stalks about three feet high, smooth, and dividing into several branches: the leaves are large, smooth, deeply cut or jagged on their edges, and embracing: the petals purple with dark bottoms; succeeded by oval smooth capsules filled with black seeds, which are sold under the name of *Maw-seed*.

Of this there are many sub-varieties: as with large double flowers, variegated of several colours; with red and white, purple and white, and some finely spotted like Carnations.

There are few plants whose flowers are so handsome; but as they have an offensive scent, and are of short duration, they are not in ge-

neral much regarded: they are annual, flowering in June.

The second species has the stem from one to two feet high, upright, round, branched, purplish at bottom, with spreading hairs, bulbous at the base: the leaves are sessile, forming a kind of sheath at bottom, hairy on both sides; the segments or leaflets unequally toothed or serrate, each tooth rolled back at the edge, callous at top, and terminated by a small spine: the peduncles long, round, upright, one-flowered, red, the hairs on it spreading horizontally. It is a native of every part of Europe, &c. flowering from June to August.

There is a variety with an oval black shining spot at the base of each petal, from which many beautiful garden sub-varieties are produced which have double flowers, white, red bordered with white, and variegated.

In the third the stalks are a foot high, and smooth: the pinnae of the leaves are deeply cut on their edges; and there are a few small leaves on the stalk shaped like the lower ones: the upper part of the stalk is naked, and sustains one large yellow flower, appearing in June; being filled with small purplish seeds. It is a native of Wales, &c.

The fourth species has a perennial root, composed of two or three strong fibres as thick as a man's little finger, a foot and a half long, dark brown on the outside, full of a milky juice, which is very bitter and acrid: the leaves a foot long, closely covered with bristly white hairs: the stems two feet and a half high, very rough and hairy, having leaves towards the lower part like the root-leaves, but smaller: the upper part is naked, and sustains at the top one very large flower, of the same colour with the common red sort. It was found in Armenia, and flowers here in May.

There are a few varieties, differing in the colour of the flowers; and it is said that the flower is sometimes double, but with us it is always single.

Culture.—All the different sorts may be increased by seeds, and the two last sorts also by parting and planting out the roots.

The seeds should be sown in the autumn, or very early in the spring, (but the former is the better season,) either in the places where the plants are to grow, or in beds, to be afterwards planted out. The first is probably the best method, as these plants do not bear removing well.

When they are cultivated for ornament, seed of the finest double sorts should be carefully provided and made use of, and be sown in patches.

In the practice of Mr. Ball in cultivating the first:

sort for the purpose of preparing opium from it, "the seed was sown at the end of February, and again the second week in March, in beds three feet and a half wide, well prepared with good rotten dung, and often turned or ploughed, in order to mix it well, and have it fine, either in small drills, three in each bed, or broadcast; in both cases, thinning out the plants to the distance of a foot from each other, when about two inches high, keeping them free from weeds." They produced from four to ten heads each, and showed large flowers of different colours. "With an instrument something like a rake, but with three teeth, the drills may, he says, be made at once." He found that the plants did not bear transplanting; as, out of 4000 which he transplanted, not one plant came to perfection.

The roots of the two last sorts may be divided in the autumn, or spring, (but the first period is the better,) leaving some root fibres to each parting, planting them out where they are to remain, as soon afterwards as possible.

In all the sorts the plants only require afterwards to be kept free from weeds, and those raised from seed properly thinned out.

They all afford ornament and variety in the clumps, borders, and other parts of pleasure grounds and gardens; and the first sort may sometimes be grown to advantage for the purpose of having the juice which it affords made into opium.

PAPAW-TREE. See **CARICA**.

PAPER-FRAMES, such as are formed with oiled paper upon a slight frame-work of thin slips of wood.

They are useful for several purposes in the early spring and summer season; such as in defending late hot-beds, and sometimes in particular natural ground beds of curious tender plants, seeds, cuttings, &c.

In making them when formed as above, either in a ridge manner, with two sloping sides, longways, or arch-fashion, in dimensions from five to ten feet in length, three to four in width, and two to three feet in perpendicular height; the wood-work is covered with large sheets of strong white paper pasted on securely, and when dry, brushed over regularly with linseed oil, to resist and shoot off the falling wet of rains and dews, and to render them more pellucid, so as to admit the rays of light and the heat of the sun in a proper degree. When thus prepared and perfectly dry, they are ready for placing over the beds, for the purposes required; in which the paper continues durable generally only one season; but the frame-work will last several years, by being fresh papered.

These kinds of temporary Frames are also useful in some of the hand-glass crops of melons, and occasionally in those of cucumbers, but more generally in the former; which after having advanced in growth, to fill and extend beyond the compass of the hand-glasses, they should be removed, and the Paper-frames placed over the bed, covering it wholly in width and length, the runners of the plants being trained out regularly along the surface; continuing them constantly over the plants, which are thereby protected from external injuries, and inclement weather, either cold or excessive rains, winds, &c., likewise from the too powerful heat of the sun. See **CUCUMIS MELO**.

They may also be used for late hot-bed cucumbers, when in want of garden-frames or hand-glasses for the purpose, being placed over the bed, at once, finally to remain: and with proper care in giving occasional air, water, and covering over the frames with mats in cold nights, and very hard rains, &c., cucumbers may be raised in a tolerable manner.

They may likewise be employed occasionally, in default of others, in the raising most of the less hardy or tenderer annuals, both in sowing them in hot-beds and warm borders of natural earth.

Paper-frames may likewise be used advantageously in pricking-out many sorts of small tender seedling plants in the hot summer months, to defend them from casual unfavourable night air, heavy rains, &c., and afford a fine growing shade from the hot rays of the mid-day sun. The same kind of frames may still further be beneficial in raising many sorts of tender exotics, from small cuttings and slips in summer, both of the woody, herbaceous and succulent kinds, either planted in hot-beds or in the natural earth, as the different kinds may require; which being covered close with them, they exclude the outward air, admit the light and influence of the sun in a proper degree, and at the same time afford a peculiar kindly shade.

They are chiefly made in the forms mentioned above, in an open manner, having the ribs or spars twelve inches asunder, first forming a bottom frame, rather stronger than the other parts, with a ridge-piece supported at a proper height, extending longways in the middle; then narrow side rafters, arranged from the bottom to the ridge rail at top, a foot distant, both for the advantage of pasting the paper regularly, and to admit a proper degree of light between them, through the paper: but when of great length, it is proper to have one or two pannels on one side, eighteen inches or two feet in width, to open outward with hinges, convenient

for admitting air, and performing other occasional culture: the whole being thus formed in the wood work, it is then proper to extend lines of packthread cross-ways of the ribs, going round each, level or even with the upper surface of the frame, continuing two or three rows a foot asunder, from the lower part upward, drawing other lines, crossing and intersecting these at the same distance, regularly between the ribs of the frame-work; which arrangement of the lines is of essential service for the more effectual support of the paper when pasted on the frame, and strengthening it against the power of winds and heavy rains. The paper for this use should be of the larger strong printing or demy kind; which, previously to pasting on the frame, should be moderately damped with water, that it may not sink in hollows after being fixed; and as soon as thus prepared it should be pasted on, sheet and sheet, in a regular manner, one large sheet and a half, or two at most, generally ranging from bottom to top, contriving to have whole ones along the ridge-rails above, extending lengthways and across, placed conveniently to join regularly with the other sheets below; and if, at the intersections of the packthreads, a small square or round bit of the same paper be pasted on the inside to the main sheets over that part of the packthread, it will give it additional strength against rain and wind.

When the paper is thus pasted on, and perfectly dry, it must be oiled over with linseed oil, either raw or boiled: the latter is however rather apt to harden the paper, and more liable to crack or break: it may be applied by means of a painter's soft clean brush, dipping lightly, and brushing the outside of the paper all over, equally in every part; then placing the frame in some dry covered shed, to remain till the whole is thoroughly dry; when it may be used.

Though these sorts of frames may be cheap, and answer many little purposes of the gardener, they are not by any means so useful as those made with glass.

PARIETARIA, a genus containing a plant of the shrubby kind for the green-house.

It belongs to the class and order *Polygamia Monœcia*, and ranks in the natural order of *Scabridæ*.

The characters are: that the hermaphrodite flowers are two, contained in a flat six-leaved involucre: the two opposite and outer leaflets larger: the calyx is a one-leaved perianthium, four-cleft, flat, blunt, the size of the involucre halved: there is no corolla, unless the calyx be called so: the stamina have four awl-shaped filaments, longer than the flowering perianthium and expanding it, permanent: anthers twin:

VOL. II.

the pistillum is an ovate germ: style filiform, coloured: stigma penciliform, capitate: there is no pericarpium: perianthium elongated, larger, bell-shaped, the mouth closed by converging segments: the seed one, ovate: female flower one, between the two hermaphrodites, within the involucre: the calyx as in the hermaphrodites: there is no corolla: the pistillum as in the hermaphrodites: there is no pericarpium: perianthium thin, involving the fruit: the seed, as in the hermaphrodites.

The species cultivated is *P. arborea*, Tree Pellitory.

It is an upright soft shrub, the height of a man: the root woody, branched, fibrous, rufescent: the stem woody, upright, round, the bark full of clinks, ash-coloured: branches and branchlets alternate, spreading, villose, pithy: the shoots red, very villose with hoary hairs: the leaves alternate, spreading, entire, nerved, three-nerved above the base, veined: nerves and veins prominent underneath, grooved above, somewhat wrinkled, the younger ones very much so, underneath villose soft, above bright green, scarcely paler beneath, from four to six inches long, and from two to four wide: the flowers commonly three, clustered, from the axil of each bracte, sessile, in the male yellow, in the female red herbaceous. According to L'Heritier, the male and female flowers are on different plants. It is a native of the Canary islands, flowering from February to May.

Culture.—This may be increased by planting cuttings of the young shoots in the summer season, watering them occasionally till they have stricken root. When the plants are well rooted, they may be removed with balls about their roots into separate pots, and have the constant protection of the green-house.

They afford variety in these collections.

PARKINSONIA, a genus containing a plant of the exotic flowering tree kind.

It belongs to the class and order *Decandria Monogynia*, and ranks in the natural order of *Lamentaceæ*.

The characters of which are: that the calyx is a one-leaved perianthium; at the base bell-shaped flattish, permanent: border five-parted: segments lanceolate-ovate, acute, coloured, reflex, almost equal, deciduous: the corolla has five petals, with claws, almost equal, spreading very much, ovate: the lowest kidney-form: claw upright, very long: the stamina have ten awl-shaped filaments, villose below, declined: anthers oblong, incumbent: the pistillum is a round germ, long, declined: style filiform, rising, the length of the stamens: stigma blunt: the pericarpium is a legume very long, round,

swelling over the seeds, (whence it is necklace-form,) acuminate: the seeds several, one to each joint of the legume, oblong, subcylindric, blunt.

The species is *P. aculeata*, Prickly Parkinsonia.

It is a small tree, with a trunk ten or twelve feet high, unarmed, even: the branches long, subdivided, flexuose, prickly, strict: the prickles two opposite at the sides of the petioles, one between them three times as long as the others, awl-shaped, upright: the leaves alternate, in fours from the same bud, pinnate, very long, linear: general petioles linear, thicker at the base, flat, somewhat convex, spreading, very smooth: leaflets extremely small, on very short petioles, ovate, smooth: racemes terminating and axillary, solitary, shorter than the leaves, erect, (eight to ten,) many-flowered: flowers alternate, scattered, yellow, on long peduncles. In Jamaica it is called *Jerusalem Thorn*. It was first introduced there from the main, but now grows wild in many parts, and in the other islands of the West Indies, where it was originally cultivated for inclosures: it seldom rises above eight feet in height, and is well supplied with strong thorns on every part: the branches are flexible and small, and the trunk seldom grows to any considerable thickness. It flowers several times in the year, and is said to bear long slender bunches of yellow flowers, hanging down like those of laburnum: they perfume the air to a considerable distance; for which reason the inhabitants of the West Indies plant them about their houses.

Culture.—It is capable of being increased by sowing the seeds in pots filled with light rich mould, early in the spring season, plunging them in a hot-bed. When the plants have attained a few inches in growth, they should be carefully removed into other small pots, separately re-plunging them in the hot-bed, shading them till fresh rooted, when fresh air should be admitted according to the warmth of the season. The only method by which these plants have been kept with success through the winter, in this climate, has been by hardening them in July and August to bear the open air; and in September placing them on shelves in the dry stove, at the greatest distance from the fire, so that they may be in a very temperate state of warmth.

These plants afford ornament among other potted plants of the stove kind.

PARTERRE, a spacious level plot of ground in the pleasure garden, divided into many little partitions of different figures and dimensions; by means of edgings or lines of dwarf-box, or by verges of grass turf, with fine gravel walks between, &c. This sort of works were formerly in great

estimation, and were commonly situated directly in the front of the house, generally the whole width and sometimes more, extending proportionably in length: and where the intermixture of the figures is artfully disposed, they strike the eye very agreeably, and afford an ornamental effect at all seasons.

The general figure of a Parterre is an oblong or long square, about as long again as broad: a level open spot in some conspicuous part, as above, is mostly chosen for the purpose: first forming a long bed or border of earth, all round, for a boundary; the internal space within this border being then traced out into various little partitions, or inclosures, artfully disposed into different figures corresponding to one another, such as long squares, triangles, circles, various scroll-works, flourishes of embroidery, and various other devices; all of which are formed either by lines of dwarf-box, with intervening alleys and tracks of turf, sand, fine gravel, small shells, &c. as above, or formed sometimes entirely of verges of fine turf, disposed into wide or narrow compartments, as the figure may require: and sometimes they consist of box-edgings, and tracks of turf together; the partitions or beds of earth formed by the tracks of box and turf, &c., being planted with some choice flowers; but no large plants to hide the form, as the regularity of it, in the artful distribution of the different figures, is intended as a decoration to the whole place long after the season of the flowers is over. Some prefer Parterres composed entirely of turf and beds of earth, perfectly even, without any other figure than the long square, forming a border of earth all round, within which are spots of grass, and beds or borders of earth of different sizes. And sometimes Parterres, with box-edgings, are formed into labyrinths or mazes; and some are made to represent coats of arms with the proper supporters. All crowded designs, however, lose their effect.

Works of this sort are now almost wholly in disuse in this country: however, for the sake of variety, they may still be admitted, though not immediately in the front of the house.

PARTING ROOTS, the practice of dividing the roots of some sorts of plants in order to their being set out; which is an expeditious mode of increasing a great number of fibrous-rooted perennial plants. A great number of herbaceous, fibrous, and tuberous-rooted perennial plants often increase by the root into large clusters or bunches, composed of numerous small slips or off-sets, particularly many of the flowery tribe, such as the campanula, perennial sunflower, golden-rod, perennial aster, polyanthus, and daisy, balm, mint, burnet, cives, and penny-

royal, with innumerable other sorts; which from one small slip or off-set of the root, often in a season or two multiply into a large cluster of such off-sets; and these clusters of roots being parted into several separate slips, with root-fibres at their bottom, and one or more buds at top, each commences a distinct plant; so that, by parting the roots in this way, one plant may instantly be multiplied into many, each of which becomes alike in growth and general habit to the original, and all flower the ensuing season in their due course; and in their turns detach from their sides all around, a due supply of off-sets for further propagation.

The best general season for Parting Roots is in the latter end of summer or autumn, after they have done flowering, and the stalks are decayed; which is in August, and the two following months; in which, when the detached off-sets are planted directly, they will take good root before winter. But in many hardy sorts it may be performed almost any time, in open weather, from September till March; and some of the tender kinds succeed best in spring. In these cases it should, however, be done before they begin to shoot forth their stalks or advance considerably in their spring shoots.

In performing the business, when any plant designed to be increased has multiplied by its roots into a cluster of off-sets, the whole may either be taken up entirely, and the root parted into as many slips as are furnished with fibres, &c., or a quantity of slips may be detached from the sides all around as the parent plant stands in the ground: in either method, the work may in many sorts be effected easily with the hand; and in others by the assistance of a knife, &c. And when it is wanted to make as great an increase as possible, the root may be parted into as many slips as may be convenient, provided each is furnished with some fibre or root-part, and crowned with one or more buds or eyes for forming shoots at top. But in the flowery tribe, when the detached off-sets are wanted for flowering as strong as possible the ensuing season, they should not be parted too small, but into middling-sized slips, where practicable; which being planted in the proper places will flower in tolerable perfection in the following season. The slips should generally be planted directly by dibble; the very small ones in nursery-beds to stand till next autumn, to acquire strength: then transplanted with balls into the places where they are to remain; but the larger ones at once where they are to grow.

This method may be practised in many sorts annually, as numbers of the herbaceous perennials multiply in one season into large bunches.

PARSLEY. See *APIUM*.

PARSNIP. See *PASTINACA*.

PARTHENIUM, a genus containing plants of the annual and perennial kinds.

It belongs to the class and order *Monoecia Pentandria*, and ranks in the natural order of *Nucamentaceæ*.

The characters are: that the calyx is a common quite simple perianthium, five-leaved, spreading: leaflets roundish, flat, equal: the corolla compound convex: corollets hermaphrodite many in the disk: females five in the ray, scarcely surpassing the others: proper of the hermaphrodites one-petalled, tubular, erect, with the mouth five-cleft, the length of the calyx: of the females one-petalled, tubular, ligulate, oblique, blunt, roundish, the same length with the other: the stamina in the hermaphrodites—filaments five, capillary, the length of the corollet: anthers as many, thickish, scarcely cohering: the pistillum of the hermaphrodite—germ below the proper receptacle, scarcely observable: style capillary, generally shorter than the stamens: stigma none: of the female, germ inferior, turbinate-cordate, compressed, large: style filiform, the length of the corollet: stigmas two, filiform, the length of the style, spreading a little: there is no pericarpium: calyx unchanged: seeds in the hermaphrodites abortive: in the females solitary, turbinate-cordate, compressed, naked: the receptacle scarcely any, flat: chaffs separate the florets, so that each female has two hermaphrodites behind.

The species are: 1. *P. Hysterophorus*, Cut-leaved Parthenium, or Bastard Feverfew; 2. *P. integrifolium*, Entire-leaved Parthenium.

The first is an annual plant, growing wild in great plenty in the island of Jamaica, where it is called Wild Wormwood; and thrives very luxuriantly about all the settlements in the low lands. It is observed to have much the same qualities with Feverfew. It flowers here in July and August.

The second species is a perennial plant, which dies to the ground every autumn, and shoots up again the following spring. It rises three feet and more, with thick, round, fleshy stems: the leaves half-embracing, hirsute, not hairy, somewhat paler underneath, with frequent oblique veins or nerves: root-leaves large and long, on keeled petioles: the flowers grow in a corymb at the ends of the stem and branches: the heads are snow-white above, like those of *Gnaphalium*, whitish green below, and villose at first. It is a native of Virginia, flowering in July, but seldom produces good seeds in this climate.

Cultura.—The first sort may be increased by

sowing the seeds on a hot-bed early in the spring; and when the plants come up, transplanting them upon another hot-bed, about five or six inches distant, giving them water and shade until they have taken new root; after which, they must have a pretty large share of fresh air in warm weather, by raising the glasses of the hot-bed every day, and be duly watered every other day at least. When the plants have grown so as to meet each other, they should be carefully taken up, preserving a ball of earth to their roots, and each planted into a separate pot filled with light rich earth; and be plunged into a moderate hot-bed till fresh rooted; after which they may be exposed, with other hardy annual plants, in a warm situation, where they will flower in July: but if the season should prove cold and wet, it will be proper to have a plant or two in shelter, either in the stove, or under tall frames, in order to have good seeds, if those plants which are exposed should fail.

The second sort may be increased by parting the roots in autumn, and be planted in the full ground, where it will abide the cold of our ordinary winters.

They afford ornament in the borders and among potted plants.

PASQUE-FLOWER. See ANEMONE.

PASSERINA, a genus containing plants of the shrubby exotic evergreen kind.

It belongs to the class and order *Octandria Monogynia*, and ranks in the natural order of *Veprculæ*.

The characters are: that there is no calyx: the corolla is one-petalled, shrivelling: tube cylindrical, slender, ventricose below the middle: border four-cleft, spreading: segments concave, ovate, blunt: the stamina have eight filaments, bristle-shaped, the length of the border, placed upon the point of the tube: anthers subovate, erect: the pistillum is an ovate germ, within the tube of the corolla: style filiform, springing from the side of the very point of the germ, the same length with the tube of the corolla: stigma capitate, hispid all over with villose hairs: the pericarpium is coriaceous, ovate, one-celled: the seed single, ovate, acuminate at both ends, with the points oblique.

The species cultivated are: 1. *P. filiformis*, Filiform Sparrow-wort; 2. *P. hirsuta*, Shaggy Sparrow-wort; 3. *P. capitata*, Headed Sparrow-wort; 4. *P. ciliata*, Ciliated Sparrow-wort; 5. *P. uniflora*, One-flowered Sparrow-wort.

The first rises with a shrubby stalk five or six feet high, sending out branches the whole length, which, when young, grow erect, but as they advance in length, they incline towards

a horizontal position; but more so, when the small shoots at the end are full of flowers and seed-vessels: the branches are covered with a white down like meal, and are closely beset with very narrow leaves in four rows, so that the young branches seem as if they were four-cornered: the flowers come out at the extremity of the young branches, from between the leaves, on every side, are small and white, so that they make no great appearance. It is a native of the Cape, flowering from the month of June to August.

The second species has shrubby stalks, which rise to a greater height than the former: the branches grow more diffused, and are covered with a mealy down: the leaves imbricate, short, thick, succulent, smooth and green on the outside, but downy on the inner: the flowers small and white, like those of the former, appearing about the same time. It is a native of Spain and Portugal.

The third has the leaves scattered: the heads terminating, globular: the peduncles tomentose, thickened: the flowers many, white, sessile without a tube: the stamens above the throat sixteen, the eight inner of which are castrated: stems shrubby, compound, with rod-like red branches: the leaves erect, acuminate: the common peduncles from the end of the branches, turbinate, tomentose. It is a native of the Cape.

The fourth species has a shrubby stalk, rising five or six feet high, sending out many branches which are naked to their ends, where they have oblong leaves, standing erect, and having hairy points: the flowers are small, white, and come out among the leaves at the end of the branches: but according to Linnaeus purple, with the throat villose. It is a native of the Cape, flowering here in June.

The fifth has a shrubby stalk, seldom rising more than a foot high, dividing into many branches, which are slender, smooth, and spread out on every side: the leaves dark-green, having the appearance of those of the fir-tree, but narrower: the flowers are larger than those of the former, and the upper part of the petals is spread open flat: they are of a purple colour, and appear about the same time as the former. It is a native of the Cape.

Culture.—All the sorts may be increased by cuttings planted in a bed of loamy earth, during the summer months, and closely covered with a bell or hand glass to exclude the air, shading them from the sun, and refreshing them now and then with water. When well rooted they may be planted out, each into a small pot filled with loamy earth; placing them in the shade

till they have taken new root; then be removed into a sheltered situation, to remain till the beginning of autumn, when they must be placed in the green-house, and treated as the myrtles. They may likewise be increased by layers.

The second sort may also be raised by sowing the seeds in autumn, soon after they are ripe, in small pots filled with light earth, plunging them into an old bark-bed under a common frame in winter: the plants rise in the spring, and must be treated like the cuttings. The seedling plants grow the most erect, and make the handsomest appearance.

This sort is capable of living abroad in common winters, in a dry soil and warm situation; but in hard frosts the plants are frequently destroyed: one or two should therefore be kept in pots, and sheltered during that season.

They afford variety among other potted green-house plants.

PASSIFLORA, a genus containing plants of the herbaceous and shrubby flowering kinds.

It belongs to the class and order *Gynandria Pentandria*, (*Pentandria Trigynia*), (*Monadelphia Pentandria*), and ranks in the natural order of *Cucurbitaceæ*.

The characters are: that the calyx is a five-parted perianthium, flat, coloured: the corolla has five petals, semilanceolate, flat, blunt, of the same size and form with the calyx: nectary a triple crown; the outer longer, encircling the style within the petals, more contracted above: the stamens have five awl-shaped filaments, fastened to a column at the base of the germ, and united at bottom, spreading: anthers incumbent, oblong, blunt: the pistillum is a roundish germ, placed on the apex of a straight, cylindrical column: styles three, thicker above, spreading: stigmas capitate: the pericarpium is a fleshy berry, subovate, one-celled, pedicelled: the seeds very many, ovate, arilled: receptacle of the seeds triple, growing longitudinally to the rind of the pericarp.

The species cultivated are: 1. *P. cærulea*, Common or Blue Passion-flower; 2. *P. incarnata*, Rose-coloured Passion-flower; 3. *P. lutea*, Yellow Passion-flower; 4. *P. serratifolia*, Notch-leaved Passion-flower; 5. *P. maliformis*, Apple-fruited Passion-flower; 6. *P. quadrangularis*, Square-stalked Passion-flower; 7. *P. alata*, Wing-stalked Passion-flower; 8. *P. laurifolia*, Laurel-leaved Passion-flower, or Water Lemon; 9. *P. multiflora*, Many-flowered Passion-flower; 10. *P. rubra*, Red-fruited Passion-flower; 11. *P. Murucuja*, Moon-shaped-leaved Passion-flower; 12. *P. Vespertilio*, Bat-winged Passion-flower; 13. *P. rotundifolia*, Round-leaved Passion-flower; 14. *P. ciliata*, Ciliated

Passion-flower; 15. *P. suberosa*, Cork-barked Passion-flower; 16. *P. holosericea*, Silky-leaved Passion-flower; 17. *P. glauca*, Glauous-leaved Passion-flower; 18. *P. minima*, Dwarf Passion-flower.

The first rises in a few years to a great height, with proper support: it may be trained up more than forty feet high: the stalks will grow almost as large as a man's arm, and are covered with a purplish bark, but do not become very woody: the shoots often grow to the length of twelve or fifteen feet in one summer, and being very slender, must be supported, otherwise they will hang to the ground, intermix with each other, and appear very unsightly: at each joint is one leaf composed of five smooth entire lobes; the middle one, which is longest, almost four inches long, and one inch broad in the middle; the others are gradually shorter, and the two outer lobes are frequently divided on their outer side into two smaller ones: their foot-stalks are near two inches long, and have two embracing stipules at their base; and from the same point issues a long clasper or tendril: the flowers come out at the same joint with the leaves, on peduncles almost three inches long; they are blue, have a faint scent, and continue only one day: the fruit is egg-shaped, the size and shape of the Mogul-plum, and when ripe of the same yellow colour. It grows naturally in Brazil.

There is a variety with much narrower lobes, divided almost to the bottom: the flowers come later in the summer: the petals are narrower, and of a purer white colour.

The second species has a perennial root: the stalks are annual, slender, rising four or five feet high: at each joint one leaf, on a short foot-stalk, having mostly three oblong lobes, but the two side ones are sometimes divided part of their length into two narrow segments, and thus becoming five-lobed; they are thin, of a light green, and slightly serrate: the flowers are produced from the joints of the stalk, at the foot-stalks of the leaves, on long slender peduncles, in succession as the stalks advance in height during the summer months: they have an agreeable scent, but are of short duration, opening in the morning, and fading away in the evening: the fruit is as large as a middling apple, changing to a pale orange colour when ripe. It grows naturally in Virginia.

The third has a creeping root, sending up many weak stalks, three or four feet high: the leaves are shaped like those of ivy, and almost as large, but of a pale green and very thin consistence: the peduncle is slender, an inch and half long: the flowers dirty yellow, not larger than a sixpence when expanded. It is

a native of Virginia and Jamaica, flowering in May and June.

The fourth species is perennial and shrubby: the stems are round; the younger ones very slightly villose, and climbing very high: the stipules are linear and acuminate: the footstalks of the leaves furnished with two pairs of glandules: the leaves ovate, smooth, and slightly serrated round their whole outline: the peduncles are one-flowered and solitary: the flowers have an extremely agreeable odour. It is a native of the West Indies, flowering from May to October.

The fifth has a thick stem, triangular, by slender tendrils thrown out at every joint rising to the height of fifteen or twenty feet: at each joint is one leaf, six inches long, and four broad in the middle, of a lively green and thin texture, having a strong midrib, whence arise several small nerves, diverging to the sides, and curving up towards the top: petioles pretty long, having two small glands in the middle: two large stipules encompass the petioles, peduncles and tendrils at the base: the peduncles are pretty long, having also two small glands in the middle: the cover of the flower is composed of three soft velvety leaves, of a pale red, with some stripes of a lively red colour; the petals are white, and the rays blue: the flowers being large make a fine appearance, but are of short duration; there is however a succession for some time: the fruit is roundish, the size of a large apple, yellow when ripe, having a thicker rind than any of the other sorts. It grows naturally in the West Indies.

In the sixth the stem is almost simple, thick, membranaceous at the four corners, somewhat hispid: the leaves are petioled, five or six inches long, entire, somewhat rugged, but without any pubescence: the tendrils very long, axillary: stipules in pairs, ovate at the base of the petioles, on which are six glands: the peduncles opposite to the petioles, thicker: the flowers very large, encompassed by a three-leaved involucre, the leaves of which are roundish, concave, entire, smooth, pale: the fruit is very large, oblong, and fleshy: the flower is much larger, though very like the above sort in colour. It is a native of Jamaica.

The seventh species is very like the preceding at first sight: the open flower has also a general resemblance; but the peduncle is cylindrical; the three divisions of the involucre small, lanceolate, with glandular serratures; the pedicel thickest at the insertion into the convex base of the flower: the five or six outer petals are oblong with an awn, the inner longer; the outer principal rays thinnest and shortest; imperfect rays in a double row, below and distinct from them a single row: no imperfect opercu-

lum; operculum partly horizontal and partly turning up to the column, then folding back down again and embracing the column, with which it is so connected that it appears inseparable, but is not joined to the column: nectary round the column, confined by the base: the column comes to the bottom of it. It is a native of the West Indies.

If this does not equal the first sort in elegance, it exceeds it in magnificence, in brilliancy of colour, and in fragrance, the flowers being highly odoriferous.

The eighth has a suffrutescent stem, with very divaricating, filiform branches: the leaves a little emarginate at the base, nerved, and very smooth, on short petioles compressed a little, having two glands under the base of the leaf: the tendrils are very long: the peduncles the length of the petioles: the three leaflets of the involucre are roundish, concave, with blunt glandular toothlets about the edge, and pale: the five leaflets of the calyx are broad-lanceolate, slightly membranaceous at the edge, horned with a point or awn, smooth, variegated on the inside with blood-red dots: petals five, the length of the calyx, narrower, acuminate, with blood-red dots scattered over them: the flowers are very handsome and odoriferous, but the fruit ovate and watery. It flowers in June and July, and is a native of Jamaica.

The ninth species has slender stalks, sending out many small branches, and climbing to the height of twenty-five or thirty feet: by age they become woody towards the bottom, and their joints are not far asunder: the leaves are on short slender petioles, three inches and a half long, and two broad in the middle, rounded at the base, but terminating in a point at top, smooth, entire, and of a lively green colour: the flowers are axillary, on long peduncles, having an agreeable odour, but seldom continuing twenty hours open. There is a succession of them from June to September, and the fruit will sometimes ripen in this climate. It grows naturally at La Vera Cruz.

The tenth has an herbaceous stem, twining round, grooved, hirsute, red: the lobes of the leaves entire, nerved, somewhat hispid, soft: the petioles round, red, villose, without glands: the tendrils subaxillary: the flowers alternate, nodding, on solitary one-flowered peduncles: the fruit spherical, marked with six lines, scarlet when ripe, hirsute. It is a native of the West Indies, flowering in April and May.

The eleventh species has an herbaceous, grooved, smooth stem: the leaves ovate or oblong, two-horned, with an intermediate bristle, three-nerved, veined, smooth, entire: dots on the back hollowed, pellucid: the petioles grooved, smooth, destitute of glands: the tendrils sub-

axillary, filiform, long: the flowers in pairs, axillary, scarlet, large: the berry ovate, the size of a pigeon's egg, and pedicelled. It is a native of the West Indies.

The twelfth has slender, striated, roundish stalks, less than a straw, of the same thickness from top to bottom, and of a brownish red colour, dividing into many slender branches: the leaves shaped like the wings of a bat when extended, about seven inches in length, or rather breadth, from the base to the top not more than two inches and a half, the upper ones smaller, the middle wider, and the lower narrower, smooth and somewhat shining; the colour in the upper ones pale, in the middle deeper, in the lower darker green, with two purple tubercles or glands towards the base, where they are connected with the petiole; which is set half an inch from the base of the leaf, three nerves springing from it, two extending each way to the narrow points of the leaf, the other rising upright to the top, where is the greatest length of the leaf: the flowers are on short round peduncles from the axils of the middle and upper leaves, white and of a middle size, about three inches in diameter when expanded: they are without scent, open in the evening or during the night, in the month of July, and finally close about eight or nine o'clock in the morning. It is a native of the West Indies.

The thirteenth species has the stem suffrutescent at bottom, subdivided, angular, grooved: the leaves semiovate, three-nerved, veined, smooth on both sides, marked behind longitudinally with pellucid dots: lobes terminated by very small bristles; the middle one a little larger than the others: the petioles short, without glands: the tendrils filiform, very long: the stipules two, opposite, awl-shaped: the peduncles axillary, filiform, an inch long: the flowers nodding, pale green, rather large: the berry egg-shaped. It is distinguished from the other sorts by its rounded leaves slightly three-lobed at top only. It is a native of Jamaica.

The fourteenth runs to a great height, and has dark-green glossy leaves: the involucre is composed of three leaves divided into capillary segments, each terminating in a viscid globule: the pillar supporting the germen is bright purple with darker spots: the petals are greenish on the outside, and red within: the crown consists of four rows of radii, which are varied with white and purple. It is a native of Jamaica.

The fifteenth species rises with a weak stalk to the height of twenty feet: as the stalks grow old, they have a thick fungous bark like that of the Cork-tree, which cracks and splits: the smaller branches are covered with a smooth bark:

the leaves are smooth, on very short petioles: the middle lobe is much longer than the lateral ones, so that the whole leaf is halbert-shaped: the flowers are small, of a greenish yellow colour: the fruit egg-shaped, dark purple when ripe. It is perennial, and a native of the West Indies, flowering from June to September.

In the sixteenth species the stalks rise twenty feet high, dividing into many slender branches, covered with a soft hairy down: the leaves are shaped like the point of a halbert, three inches long, and an inch and half wide at the base, light green, soft and silky to the touch, standing obliquely to the foot-stalks: the flowers are not half so large as those of the common or blue Passion-flower: the fruit small, roundish, yellow when ripe, leaves ovate, tomentose on both sides: lateral lobes short; with an obsolete gland underneath behind the sinus of the lobe. It grows naturally at La Vera Cruz, flowering most part of the summer.

In the seventeenth, the whole plant is very smooth and even: the leaves glaucous underneath, undotted: the petioles furnished with two or four glands below the middle: the stipules acute, quite entire, more than half an inch in length: the flowers are sweet. It is a native of Cayenne.

The eighteenth species has the stem twining, simple, becoming corky at the base with age, round, smooth: the leaves subpeltate, subcordate: lateral lobes almost horizontal; all acute, nerved, smooth on both sides: the petioles short, round, reflex, smooth: the glands two, opposite, small, sessile, concave, brown, in the middle of the petioles: the stipules two, opposite, awl-shaped, by the side of the petioles: the tendrils long, between the petioles: peduncles axillary, solitary, longer than the petioles, loose, one-flowered: the flowers small, whitish: the berry small, blue, egg-shaped.

Culture.—In all the sorts it is either by seeds, layers, or cuttings, according to the kinds.

The first or hardy sort is capable of being raised either by seeds, layers, or cuttings: the seed should be sown in the early spring, as March, in large pots, half an inch deep, either plunging them in a warm border, and as the weather becomes warm moving them to the shade; or in a hot-bed, which will forward the germination of the seed more fully, and the plants will rise sooner; which should afterwards be hardened gradually to the open air till the autumn, and then placed under a garden-frame for the winter, to have shelter from frosts, and in the spring planted out in pots, or some in the nursery; and in a year or two they may be transplanted where they are to remain, against some warm south wall.

The layers should be laid down from some of the branches in the common way in the spring, when they will readily emit roots, and make proper plants by autumn; when, or rather in spring following, they should be taken off and transplanted either into pots in nursery rows, or where they are to remain.

The cuttings should be made in February or March from the strong young shoots, in length from about eight to ten or twelve inches, planting them in any bed or border of common earth, giving frequent watering in dry weather, and when sunny and hot, if in a situation exposed to them, a moderate shade of mats will be of much advantage. They will emit roots at bottom, and shoots at top, and become good plants by autumn, allowing them the occasional shelter of mats, &c. during the winter's frost; and in the spring let them be planted out. If a quantity of these cuttings be planted close, and covered down with hand-glasses, it will forward their rooting; observing, however, when they begin to shoot at top, to remove the glasses, in order to admit fresh air.

The second and third, or green-house kinds, may be increased by seed, layers, and parting the roots: the seed, obtained from America, should be sown in pots in March or April, plunging them in a hot-bed to raise the plants, which afterwards inure to the open air in summer, giving them the shelter of a green-house or frame in winter; and in the spring following plant some out in pots, placing them among the green-house plants; and others may be planted in the full ground, under a warm fence, to take their chance.

The layers should be made in the summer from young shoots, which will readily grow, and become good plants for potting off in autumn. The parting the roots should be done in spring, before they begin to shoot. The second sort multiplies exceedingly by its creeping roots; which should be divided into slips, and planted in a bed of rich earth till autumn, when some should be transplanted into pots for occasional shelter in winter.

All the other more tender stove kinds are capable of being increased by seeds, layers, and cuttings: The seeds are procured chiefly from abroad; and should be sown in spring in pots, plunging them in a hot-bed, or in a stove bark-bed: the plants soon appear, which, when three inches high, should be pricked out in separate small pots, giving water, and re-plunging them in the hot-bed, occasionally shading them till rooted: as they advance in growth, they should be shifted into larger pots, and be retained constantly in the stove.

The layers should be made from the young branches in the spring or beginning of summer, which will readily grow, and be fit to pot off separately in autumn.

The cuttings should be made in the spring or summer, from the young shoots, planting them in pots, plunging them in the bark-bed, and giving water frequently; when most of them will take root, and be fit to pot off singly in autumn.

In respect to their general culture; as in severe winters, in the first sort, the branches, if not duly protected, are sometimes killed, it is advisable at such times, whilst the plants are young in particular, to give them the shelter of mats during the inclement season, and protect their roots with dry litter laid over the ground; carefully uncovering their branches as soon as the frost breaks: this covering, however, is only necessary in very severe frosts.

The green-house sorts should generally be potted, to move to shelter in winter, either of a green-house, or deep garden-frame: some plants of each sort may also be planted in the full ground, in a warm border, to take their chance; covering the ground over their roots in severe weather; and in the different orders of planting, placing stakes for the support of their climbing growth in the summer. And all the stove kinds must constantly be kept in pots, placed in the stove, and for the most part plunged in the bark-bed; placing strong stakes for the purpose of training the branches to, and managing them as other stove-plants of a similar growth. See STOVE-PLANTS.

The first sort is highly ornamental in the open ground when trained against southern walls, &c.; and those of the green-house, and stove kinds, among other plants in these collections.

PASTINACA, a genus containing plants of the herbaceous esculent kind.

It belongs to the class and order *Pentandria Digynia*, and ranks in the natural order of *Umbellatæ* or *Umbelliferae*.

The characters are: that the calyx is an universal umbel, manifold, flat: partial manifold: involucre universal none: partial none: perianthium proper obsolete: the corolla universal uniform: florets all fertile: proper of five lanceolate involute entire petals: the stamina have five capillary filaments: anthers roundish: the pistillum is an inferior germ: styles two, reflex: stigmas blunt: there is no pericarpium: fruit compressed flat, elliptic, bipartite: the seeds two, elliptic, girt round the edge, almost flat on both sides.

The species cultivated are: 1. *P. sativa*, Common Parsnep; 2. *P. Opopanax*, Rough Parsnep.

In the first, in the wild plant, the root is biennial, simple, whitish, putting forth some large fibres from the side: the stem single, three or four feet high, erect, rigid, angular, pubescent, hollow, branched: the leaves alternate, smaller than those of the cultivated kind, and of a darker green; in open situations pubescent, especially the root-leaves: the flowering-branches come out from the axils of the leaves from top to bottom, supporting umbels which are smaller than that which terminates the stem: the flowers small, yellow, with inflex regular petals.

It is a native of most parts of Europe; but the garden or cultivated variety has smooth leaves, of a light or yellowish green colour, in which it differs from the wild plant: the stalks also rise higher, and are deeper channelled: the peduncles are much longer, and the flowers of a deeper yellow colour: the roots are sweeter than those of carrots, and are much eaten by those who abstain from animal food in Lent, or eat salt-fish; and are highly nutritious. Hogs are fond of these roots, and cattle will eat them.

The second species has a perennial root, as thick as the human arm, yellow, branched: the branches an inch or an inch and half in thickness, a foot and half in length, tubercled, with a corky bark: the stem from three feet to the height of a man, the thickness of a finger, striated, covered at the base with scarioso membranaceous scales, like the ferns; in other parts very smooth and shining; angular at top, especially at the branches. Primary (or root) leaves quite simple, cordate, acutely crenate: the others ternate or quinate, with the end leaflet always cordate and very large; the lateral ones obliquely cordate, with the upper lobe shorter: the lowest stem-leaves more compound, considered as a whole triangular, two feet long, bipinnate, having five pinnules on each side; the lowest pinna pinnate, commonly with five leaflets, the end one cordate, the rest sessile and obliquely cordate: the leaflets are an inch to two inches long; the other pinnules are first ternate, then simple. The other stem-leaves decrease, and are first quinate, next ternate, and at the branches simple. Petiole of the root-leaves from the sheath to the first pinna flattish above and thence angular-keeled; on the contrary, that of the branch-leaves is furrowed. Sheaths wide striated, in the root-leaves very strigose: in the stem-leaves smooth. All the leaflets are hairy, especially at the back. At the flowering-branches there are spathaceous sheaths, which are naked, or destitute of leaves. The umbelliferous branches are very smooth; first alternate, erect, then two, three, or four

together in a sort of whorl, two or three inches long, with one or two spathaceous leaflets towards the middle, or at the top. The universal umbels have usually seven or eight rays, an inch long, of a yellowish green colour: the fruits flat, with the rim thicker, three or four lines in diameter, and a little longer: the juice is yellow, bearing no marks of a resinous or aromatic principle. It flows out where either the leaf or stalk is broken. They are both very rough; the former dark green, the latter seven or eight feet high: the stalks divide towards the top into many horizontal branches, each terminated by a large umbel of yellow flowers; which appear in July. It is a native of the south of Europe.

It commonly ripens its seeds in this climate, and its juice manifests some of the qualities discovered in the officinal *Opopanax*: but it is only in the warmer regions of the East, where this plant is also a native, that the juice concretes into this gum-resin. It is obtained by means of incisions made at the bottom of the stalk.

Culture.—In the first sort it is easily effected by sowing fresh seed in the latter end of February, or beginning of the following month, upon a bed prepared in a spot of the best light, rich, deep soil, in one of the most open airy quarters of the garden, by being trenched one full spade deep at least, or if two the better, provided the depth of good staple admit, that the roots may have a due depth of loose soil to run down straight to their full length. And if the ground be previously trenched up in rough ridges in winter, especially where stiff or wet, and lie exposed some time to the sun and air, it will be much improved for this purpose. At the time of sowing, the ground should be made level and even on the surface, but not raked till after the seed is sown, which should be performed while the ground is fresh stirred, or before the surface becomes too dry, so as, in raking, the clods will readily fall under the rake to bury the seed regularly.

The seed should be sown broad-cast thinly, either all over the surface, or the ground may be divided into four-feet-wide beds, as most convenient, but for large quantities the former is the most eligible practice. As soon as the sowing is done, if light ground, it is the practice with some to tread down the seeds evenly, and finish with an even good raking, to cover all the seeds equally, smoothing the surface. In about three weeks the seeds begin to germinate, and the plants soon appear above ground. When they are two or three inches high, they should be thinned to regular distances, and cleaned

from weeds; which may be done either by hand or small-hoeing; but the latter is preferable for the benefit of the crop, and considerably the most expeditious: it should generally be performed by a three- or four-inch hoe. Dry weather should be chosen for the purpose, and the plants cut out to about ten or twelve inches distance, as they should have large room, cutting up all weeds as the work proceeds. After this, no more culture is required till the future progress of the weeds renders another hoeing necessary; and probably another repetition may also be required, till the plants are in full leaf, when they cover the ground, and bid defiance to any further interruption from weeds.

In the autumn, about October, the roots will be arrived nearly at their full growth; when the leaves begin to turn yellow and decay, which is a certain sign of their maturity: they may then be dug up for use, as they are wanted.

These roots may either remain in the ground all winter, and be taken up as wanted, or a quantity may be dug up in autumn, and their tops pared off close, and then buried all winter in sand, in a shed or other dry place, to be ready at all times for use: some should also be left in the ground for spring service, as January or the beginning of February, digging them up just before they begin to shoot, and laying them in the sand; as by taking them up at this time, it retards their effort for shooting, so as that they continue in tolerable perfection until the latter end of April or longer.

In order to have parsneps in due perfection, great care is necessary to save seed only from some of the finest rooted plants; for which purpose, a quantity of the large, long, straight roots should be selected, trimming off their leaves, and planting them in rows three feet asunder, and two distant in the lines, about an inch deep over their top; in which method they will shoot up strong in spring for flowering, and ripen seed in the latter end of August, or early in September; when in a dry day, the umbels of seed should be cut off and spread upon mats to dry and harden, afterwards thrashing out the seeds, and putting them up in bags for use.

The second sort may be raised, by sowing the seed in the places where the plants are to remain, at the same season as the above; keeping the plants afterwards properly thinned and clear from weeds.

The first is an useful esculent root, that contains a large proportion of nutritious matter; but the latter is chiefly cultivated for affording variety in the borders or other parts of pleasure-grounds.

PELARGONIUM, a genus containing plants of the fine shrubby under shrubby evergreen and herbaceous perennial kinds for the greenhouse.

It belongs to the class and order *Monadelphia Heptandria*, and ranks in the natural order of *Germinales*.

The characters are: that the calyx is a one-leaved perianthium, five-parted: segments ovate, acute, concave, permanent, upper segment ending in a capillary nectariferous tube, decurrent along the peduncle: the corolla has five petals, obcordate or ovate, spreading, large, irregular: the stamina have ten awl-shaped filaments, united at the base, spreading at top, unequal in length, all shorter than the corolla, three of them (seldom five) castrated: anthers seven, oblong, versatile: the pistillum is a five-cornered germ, beaked: style awl-shaped, longer than the stamens, permanent: stigmas five, reflex: the pericarpium is a five-grained capsule, beaked, the cells opening inwards: the beak spiral, bearded on the inside: the seeds solitary, ovate-oblong.

The species cultivated are: 1. *P. alchemilloides*, Lady's-mantle-leaved Crane's-bill; 2. *P. odoratissimum*, Sweet-scented Crane's-bill; 3. *P. grossularioides*, Gooseberry-leaved Crane's-bill; 4. *P. coriandrifolium*, Coriander-leaved Crane's-bill; 5. *P. carnosum*, Fleishy-stalked Crane's-bill; 6. *P. ceratophyllum*, Horn-leaved Crane's-bill; 7. *P. gibbosum*, Gouty Crane's-bill; 8. *P. radula*, Multifid-leaved Crane's-bill; 9. *P. papilionaceum*, Butterfly Crane's-bill; 10. *P. inquinans*, Scarlet-flowered Crane's-bill; 11. *P. zonale*, Common Horse-shoe Crane's-bill; 12. *P. bicolor*, Two-coloured Crane's-bill; 13. *P. vitifolium*, Balm-scented Crane's-bill; 14. *P. capitatum*, Rose-scented Crane's-bill; 15. *P. glutinosum*, Clammy Crane's-bill; 16. *P. cucullatum*, Hooded Crane's-bill; 17. *P. cordatum*, Heart-leaved Crane's-bill; 18. *P. echinatum*, Prickly-stalked Crane's-bill; 19. *P. tetragonum*, Square-stalked Crane's-bill; 20. *P. betulinum*, Birch-leaved Crane's-bill; 21. *P. glaucum*, Spear-leaved Crane's-bill; 22. *P. acetosum*, Sorrel Crane's-bill; 23. *P. scabrum*, Rough-leaved Crane's-bill; 24. *P. ternatum*, Ternate Crane's-bill; 25. *P. tricolor*, Three-coloured Crane's-bill.

The first sends out several herbaceous stalks about a foot and half in length. The flowers are

pale blush-colour, several together upon very long peduncles: and there is a succession of them during all the summer months.

There is a variety with a dark circle in the middle of the leaves.

The second species has a very short fleshy stalk, dividing near the ground into several heads, each having many leaves, on separate footstalks from the heads; they are soft and downy, and have a strong scent like aniseed. From these heads come out several slender stalks, near a foot in length, prostrate, with rounder leaves than those near the root, but of the same texture and odour: the flowers are produced from the side of these stalks, three, four, or five standing together upon slender peduncles; they are white, but being small they make little appearance.

The third has the stem prostrate, four-cornered, smooth; as is also the whole plant, which is biennial, sending out a great number of very slender trailing stalks, extending a foot and half in length: the leaves are small, marked with lines: the peduncles are capillary, with two or three small flowers, of a pale flesh-colour. They continue in succession all the summer.

The fourth species is an annual or rather biennial plant, with branching stalks near a foot high: the lower leaves stand upon long footstalks, but those on the upper part sit close to the stalks: the flowers stand upon naked peduncles, which proceed from the side of the stalks, on the side opposite to the leaves: they grow three or four together upon short separate pedicels: they are of a pale flesh-colour, and appear in July.

The fifth has a thick fleshy knotted stalk, rising about two feet high, sending out a few slender fleshy branches, thinly set with leaves, which on the lower part of the stalk are petioled, but above sessile: the flowers are produced in small clusters at the ends of the branches: the petals are narrow and white, making no great appearance; they continue in succession most part of the summer.

The sixth species flowers in May, and continues to do so during most of the summer months: the seeds ripen in this climate. It is a native of the South-west coast of Africa.

The seventh has a round fleshy stalk with swelling knots at the joints, rising about three feet high, and sending out several irregular smooth branches: the leaves are thinly disposed, smooth, fleshy, gray, ending obtusely, and standing on short footstalks: the flowers four or five on a peduncle: the petals dark-purple, having a very agreeable scent in the evening: it flowers most part of the summer.

The eighth species has a shrubby stem, covered with an ash-coloured bark, branched, two feet high: the leaves are numerous, alternate, nearly equal to the petioles, very deeply five-cleft: the segments pinnate and bipinnate, linear: stipules wide, acuminate and shrivelling: the peduncles axillary, solitary, with one, two, or three flowers: involucre generally five-cleft, shrivelling. The whole plant has a strong smell of turpentine. The leaves in the young plants are often three inches long; but in old ones only one third of the size, and more numerous. It has the name *Radula*, from the rough rasp-like surface of its leaves. It flowers from March to July.

There are two varieties, a larger and a smaller: and as it is readily raised from seeds, it affords many seminal varieties.

The ninth rises with an upright shrubby stalk seven or eight feet high, sending out several side branches with large, angular, rough leaves, on short footstalks: the flowers are produced in large panicles (umbels) at the ends of the branches: the two upper petals, which are pretty large, turn upwards, and are finely variegated; but the three under ones are very small, and, being bent back, are screened from sight, unless the flower be viewed near. It flowers from April to July.

The tenth species rises with a soft shrubby stem to the height of eight or ten feet, sending out several branches, which are generally erect: the leaves of a thick substance, and a lucid green, on pretty long footstalks, covered with soft hairs on their under side: the flowers are in loose bunches (umbels), on long, stiff, axillary peduncles: the corolla bright scarlet: the flowers make a fine appearance, and there is a succession of them during all the summer months.

The eleventh rises with a shrubby stalk four or five feet high, and divides into a great number of irregular branches, so as to form a large bush, frequently eight or ten feet in height: the leaves are indented on the edge in several obtuse segments, cut into short teeth; there is a purplish curved zone in form of a horse-shoe, from one side of the base to the other, corresponding with the border; and when gently rubbed, the leaves have a scent like scalded apples: the flowers are produced in pretty close bunches, on axillary peduncles, five or six inches in length, coming out towards the ends of the branches; they are of a reddish purple colour, and continue in succession great part of the summer.

There is a variety with fine variegated leaves, and the flowers vary much in colour from

purple, through the different shades of red to high scarlet.

The twelfth species has the stem shrubby, twisted, covered with an ash-coloured bark: the branches round, villose, sub-herbaceous, a foot long: the leaves opposite, on long petioles, glaucous, rugged; lobes curled, toothed: the stipules almost embracing, acuminate: the common peduncle often opposite to a leaf, or lateral, sometimes axillary, longer than the leaf: involucre one-leaved, many-parted, shrivelling; rays about thirteen, scarcely an inch long. It is remarked by Jacquin, that the whole has a very strong smell: and Curtis says that it obviously differs from all the other species in the particular shape of its leaves, and the colour of the flowers, which are usually of a rich and very dark purple edged with white. It flowers from June to August.

The thirteenth species rises with an upright shrubby stalk to the height of seven or eight feet, sending out many pretty strong branches: the leaves are somewhat like those of the vine; the lower on long petioles, the upper on short ones; when rubbed, they have a scent of balm: the flowers grow in compact clusters, on the top of long, naked, axillary peduncles, rising much higher than the branches; being small and of a pale blue colour, making no great figure; but containing a succession for most part of the summer.

The fourteenth rises with a shrubby stalk four or five feet high, dividing into several weak irregular branches: the leaves are divided into three unequal lobes, which are hairy, and waved on their edges; they are placed alternately, and their footstalks are hairy: the flowers grow in close roundish heads, forming a sort of corymb; are of a purplish blue colour, and continue in succession a great part of the summer: the leaves, when rubbed, have the odour of dried roses.

The fifteenth species has a shrubby stem, covered with a gray bark, three feet high and more; branches declining and decumbent, green, clammy, as is the whole plant: the leaves are alternate, the uppermost sometimes opposite, often shorter than the petioles, large, acute, sinuate: the stipules wide-acuminate, shrivelling: the common peduncles axillary, lateral, or opposite to a leaf, erect, solitary, longer than the leaves: involucre five-leaved, the leaflets ovate-acute, shrivelling: rays from three to eight, half an inch long: the middle of the leaf is generally stained with purple. It flowers in May and June, continuing to September.

Several varieties have been produced from seed.

The sixteenth rises with a shrubby stalk eight or ten feet high, sending out several irregular branches: the leaves are roundish, with the sides erect, so as to form a hollow or hood, whence termed cowlid; are heart-shaped at the base, or kidney-shaped, and from the footstalk run many nerves arising from a point, but diverging towards the sides; the borders are sharply indented; those on the lower part of the branches have long footstalks, and are placed without order on every side, but those on the upper part have shorter footstalks, and stand opposite: the flowers are produced in large panicles (or umbels) on the tops of the branches, of a purple blue colour. It flowers from June to September.

The seventeenth species has a shrubby branched stem, when young red, when very young green and villose, when old covered with an ash-coloured bark: the leaves are alternate, almost equal to the petioles, tomentose, whitish underneath: the stipules subovate: the flowers at the ends of the stem and branches in numerous umbels. It flowers from March to July.

There are several varieties.

The eighteenth has the stalk green, surface smooth and somewhat glossy, beset with spines which bend back and terminate in brownish weakish points; these appear to have been primarily the stipules, which become thus fleshy and rigid: the leaves are on long footstalks, veiny, soft and downy, especially on the under side, which is of a much lighter colour than the upper: the flowering stem proceeds from the summit of the stalk, and is a foot or more in height: as it advances it throws out its branches or peduncles, ultimately about five in number, each of which has a leaf at its base, similar to the other leaves of the plant, but smaller, and terminates in an umbel of seven or eight flowers of a spotted purple colour. In its habit it somewhat resembles the preceding. It flowers from May to September.

It varies with petals of a rich purple colour, in which the spots are similar, but not so conspicuous.

The nineteenth species has angular stems, angles four, sometimes three, succulent, as is the whole plant, procumbent when they shoot out into length, at first hairy, afterwards very smooth, much branched, and three feet high: the leaves alternate, almost equal to the petioles, orbiculate, five-lobed; the younger villose, tooth-crenate, violate-coloured underneath, and above having a dark red zone; the older crenate, fleshy, dark green, with a few villose hairs, and frequently with a zone: the stipules short, semicircular, spreading, shrivelling: the pe-

duncles axillary, erect, rugged; with four subovate stipules at the forks. Mr. Curtis observes that a vein of singularity runs through the whole of this plant: its stalks are unequally and obtusely quadrangular, sometimes more evidently triangular: its leaves few and remarkably small: its flowers, on the contrary, are uncommonly large, and, what is more extraordinary, have only four petals; previous to their expansion the body of filaments is bent so as to form a kind of bow.

There is a variety with beautifully coloured leaves.

The twentieth has a shrubby stem, four or five feet high, sending out several branches: the peduncles long, coming out from the side of the branches: the flowers vary considerably both in size and colour: its foliage is different from that of the other sorts, and, as its name imports, like that of the birch-tree. It flowers most part of the summer.

In the twenty-first, the whole plant is very smooth, glaucous, and in a manner whitish: the stem shrubby, with round, rod-like, declining branches, two feet high: the leaves opposite, often shorter than the petioles, which are round and erect: the stipules lanceolate-acuminate, fleshy, deciduous: the peduncles alternately axillary, very long, one- or two-flowered. It flowers from June to August.

The twenty-second species has a shrubby stem, six or seven feet high, sending out several side branches: the leaves of a gray colour, and having an acid taste like sorrel: the peduncles axillary, long, sustaining three or four flowers, with narrow unequal petals, of a pale blush-colour, with some stripes of a light red: the flowers continue in succession most part of the summer.

There is a variety with scarlet flowers raised from seed.

The twenty-third has a shrubby stem, round, three or four feet high, the thickness of a finger, upright, of a reddish bay colour, branching from the axils, very rough, as is the whole plant, but becoming smooth with age: the leaves on long petioles, very widely wedge-shaped, three-nerved, acute, stiffish, alternate, except the upper ones next the flowers, which are opposite, the lower ones seven or eight inches in length reckoning the petioles; the lobes gashed or thinly toothed, but sometimes quite entire: the stipules small, ovate-acuminate, on each side next the petioles: the common peduncles terminating and axillary, short, sustaining commonly from four to six flowers, of a purple rose-colour, with dark blood-red spots. It flowers from August to November.

The twenty-fourth has a suffrutescent stem,

dichotomous, round, purple, villose, erect, two feet high and more: branches simple, short, resembling the stem: the leaves rigid, strigose-rugged, an inch long: serratures purplish: the petioles villose, the length of the leaves: the stipules two or more, ovate-acute, concave, a line in length: the flowers lateral and terminating, unlobed: involucres lanceolate, purple, subciliate. It differs materially from the other sorts in the unusual roughness of the stalks, as well as in its whole habit.

The twenty-fifth species, which is but newly introduced, scarcely exceeds a foot in height, growing up with a shrubby stem, and spreading widely into numerous flowering branches, so much disposed to produce flowers in a constant succession, that during most of the summer the plant is loaded with a profusion of them. For the most part they go off without seed; and when any is produced, there is generally one perfect and four abortive. The whole plant is covered with short white hairs, which give to the foliage a somewhat silvery hue. The two uppermost petals are of a beautiful red, having their bases nearly black; the three lowermost are white.

Most of the above species are natives of the Cape.

There are also many other species that may be cultivated.

Culture.—All the sorts may be increased by seeds, which should be sown in the early spring in pots filled with kitchen garden mould, plunging them in a moderate hot-bed. The plants soon appear; when they should have fresh air as much as possible, to prevent their being drawn up weak. When the plants have attained some growth, they should be removed into separate small pots filled with the same sort of earth, replunging them in the hot-bed till fresh rooted, and giving proper shade. They should afterwards be gradually inured to the open air, in order to be placed out in it in the summer season in a sheltered situation.

They may also be raised in the open ground, without the hot-bed, but not so well.

But they are more commonly increased, especially the shrubby sorts, by cuttings of the young branches, which should be planted in a shady border in the summer, or in pots, and plunged in any hot-bed; which is the better method. When well rooted they may be taken up, and planted into separate pots, placing them in the shade if they have taken new root; after which they may be removed into a sheltered situation, and be treated in the same manner as the seedling plants. The fifth, seventh, and fifteenth sorts have more succulent stalks than the others: the

cuttings should therefore be planted in pots filled with the same sort of earth, and plunged into a very moderate hot-bed, where they may be shaded from the sun in the heat of the day, and have but little water; for these are very apt to rot with much moisture. When these are well rooted, they may be removed, and planted in separate pots filled with the same sort of earth, and placed in the shade till they have taken new root; then they may be removed into a sheltered situation, where they may remain till autumn. These sorts should be sparingly watered, especially in the winter season, as they are apt to take a mouldiness with moisture, or in a damp air. They thrive much better in an airy glass-case than in a green-house, as in the former they have more sun and air than in the latter. But all the other shrubby sorts are proper for the green-house, where they only require protection from frost, but should have a large share of free air when the weather is mild. They require water every week, in mild weather once or twice; but it should not be given them in too great plenty, especially in frosty weather. These plants should be hardened in the spring gradually, and towards the middle or end of May be taken out of the green-house, and at first placed under the shelter of trees, where they may remain a fortnight or three weeks to harden; and then be removed into a situation where they may be defended from strong winds, and enjoy the morning sun till eleven o'clock, where they will thrive better than in a warmer situation. And as these sorts grow pretty fast, they soon fill the pots with their roots; and when they stand long unremoved in summer, they frequently put out their roots through the holes at the bottom of the pots into the ground, when the plants grow vigorously; but if suffered to continue long in this manner, it is difficult to remove them; as, if their roots be torn off, all the younger branches decay, and the plants are frequently killed. The pots should therefore be moved once in a fortnight or three weeks, in the summer months, and the roots which may be then pushing through the holes cut off, to prevent their striking into the ground.

They require also to be new potted at least twice in the summer; the first time after they have been three weeks or a month out of the green-house; the second towards the end of August, or the beginning of September, that the plants may have time to establish their new roots before they are removed into the green-house. When this is performed, all the roots on the outside of the balls of earth should be carefully pared off, and as much of the old earth drawn away from the roots, as can be done with safety

to the plants; then, where they require it, they should be put into pots a size larger than those out of which they were taken, putting a quantity of fresh earth into the bottom of each pot, placing the plants upon it, being careful that the ball about the roots of the plant be not so high as the rim of the pot, that some room may be left to contain the water which may be given to them. Then the cavity all round the ball should be filled up with fresh earth, be gently pressed down, and the bottom of the pot beaten upon the ground, to settle the earth; the plant being then well watered, and the stem fastened so as to prevent the wind from displacing the roots before they are fixed in the new earth.

Where such mould as has been mentioned cannot be procured, fresh hazel loam from a pasture, mixed with a fourth or a fifth part of rotten dung; or, where the earth is inclinable to bind, a mixture of rotten tan; and, where light and warm, a mixture of neat's-dung may be employed. This compost should be mixed three or four months before it is used, and be turned over three or four times, that the parts may be well incorporated.

The shrubby sorts require to be looked over frequently during the winter, while they are in the green-house, to pick off all decayed leaves from them, which if left on will not only render the plants unsightly, but by their falling off make a litter among the other plants; and if they are suffered to rot in the house, they occasion a foul, nasty, damp air, which is very prejudicial to all the plants.

The first sort from having herbaceous stalks is best increased by seeds, though cuttings of it will take root.

And the second sort may not only be propagated by seeds, but also from heads slipped off from the short fleshy stalk; which should have their lower leaves stripped off, and be then planted single in a small pot; or where the heads are small, two or three may be put into one pot; plunging them into a very moderate hot-bed, shading and refreshing them gently with water. They take root in a month or five weeks; when they should be hardened gradually to the open air, where they may remain till autumn, when they must be removed into shelter, as in the other kinds.

The sixth kind is capable of being increased both by seeds and cuttings, but is found to be more tender than many other sorts, and more liable to be injured by damps. The eighth species is readily increased by cuttings; but the twelfth is more difficultly raised in this way. The fifteenth is easily raised by cuttings, and

sometimes by seeds: and the seventeenth readily strikes from cuttings: the eighteenth produces seeds, but is more usually increased by cuttings: and the nineteenth and twentieth are readily propagated in the same way: the twenty-first is likewise raised from cuttings, but they are not very free in striking: the twenty-fourth is raised in this manner without difficulty: but in the twenty-fifth, from the branches running out speedily into flowering stalks, few are formed proper for cuttings, and these are struck with difficulty.

All these plants are highly ornamental, and afford considerable variety in collections of green-house plants.

PELLITORY, BASTARD. See *ACHILLEAS*.

PELLITORY OF SPAIN. See *ANTHEMIS*.

PENNY-ROYAL. See *MENTHA PULEGIUM*.

PENTAPETES, a genus comprising a plant of the exotic kind, for the stove.

It belongs to the class and order *Monadelphia Dodecandria*, and ranks in the natural order of *Columniferae*.

The characters are: that the calyx is a double perianthium: outer three-leaved, one-sided, caducous: leaflets linear, acuminate: inner one-leaved, five-parted, permanent: segments lanceolate, acuminate, spreading, longer than the corolla: the corolla has five petals, roundish, spreading, fastened to the pitcher of stamens: the stamina have fifteen filaments, filiform, upright, shorter than the corolla, united below into a pentagon pitcher, but free above: anthers sagittate, upright: ligules five, linear-lanceolate, petal-shaped, upright, each between every three stamens, springing from the pitcher: the pistillum has an ovate germ: style filiform, thickened above, striated, longer than the stamens, permanent: stigma obsoletely five-toothed: the pericarpium is a membranaceous capsule, subglobular, acuminate, five-celled, five-valved: partitions contrary: the seeds eight, ovate, acute, four on each side, fastened within side to the partition.

The species is *P. Phœnicea*, Scarlet-flowered Pentapetes.

It is an annual plant, which dies in the autumn soon after it has ripened seeds: it has an upright stalk from two to near three feet high, sending out side branches the whole length: those from the lower part of the stalks are the longest: the others gradually diminish, so as to form part of a pyramid. They are garnished with leaves of different forms: the lower leaves, which are largest, are cut on their sides towards the base into two side lobes which are short, and the middle is extended two or three inches

further in length, so that the leaves greatly resemble the points of halberts in their shape; they are slightly serrate, and of a lucid green on their upper side, but paler on their under, standing upon pretty long footstalks: the leaves which are on the upper part of the branches are much narrower, and some of them have very small indentures on their sides; they sit closer to the stalks, and are placed alternately: the flowers are axillary; they come out for the most part singly, but sometimes there are two arising at the same place from the side of the footstalk of the leaves: the peduncle is short and slender; they are of a fine scarlet colour, appearing in July. It is a native of India.

Culture.—This plant may be increased by sowing the seeds upon a good hot-bed early in March; and when the plants are fit to remove there should be a new hot-bed prepared to receive them, into which must be plunged some small pots filled with good kitchen-garden earth; into each of which one plant should be put, giving them a little water to settle the earth to their roots, shading them from the sun till they have taken new root; when they should be treated in the same way as other tender exotic plants, admitting the free air to them every day in proportion to the warmth of the season, and covering the glasses with mats every evening. When the plants are advanced in their growth so as to fill the pots with their roots, they should be shifted into larger pots, filled with the same sort of earth as before, and plunged into another hot-bed, where they may remain as long as they can stand under the glasses of the bed without being injured; and afterwards they must be removed either into a stove or a glass-case, where they may be screened from the cold, and in warm weather have plenty of fresh air admitted to them.

These plants are sometimes turned out of the pots, when they are strong, and planted in warm borders; where, if the season prove very warm, the plants will flower tolerably.

PENTSTEMON, a genus containing plants of the hardy herbaceous flowering kind.

It belongs to the class and order *Didynamia Angiospermia*, and ranks in the natural order of *Personateæ*.

The characters are: that the calyx is a one-leaved perianthium, five-parted, permanent: segments lanceolate, almost equal: the corolla one-petalled, two-lipped: tube longer than the calyx, gibbous above at the base, wider at top, and there ventricose underneath: upper lip upright bifid; segments ovate, blunt, shorter than the lower lip: lower lip three-parted; segments ovate, blunt, bent down, shorter than the tube:

the stamina have four filiform filaments, diverging at the tip, inserted into the base of the tube, and shorter than it; the two lower longer: anthers roundish, distant, included, bifid; with the lobes divaricating: the rudiment of a fifth filament between the upper ones inserted into the tube, the same length with the stamens, filiform, straight, bearded above at the tip: the pistillum is an ovate germ: style filiform, the length of the tube, bent down at the tip: stigma truncate: the pericarpium is an ovate capsule, acute, compressed, two-celled, two-valved; the seeds numerous, subglobular: the receptacle large.

The species cultivated is *P. levigata*, Smooth Pentstemon.

It has a perennial, creeping, fibrous, white root: the stem a foot and half high and more, round, purple below, brachiate: the lower leaves ovate-acuminate, quite entire, petioled, sometimes purple underneath, on petioles winged to the base: the stem-leaves ovate-lanceolate, opposite, embracing, toothfretted, smooth on both sides: the flowering branches in a manner dichotomous, with the flowers two together: the corolla pale purple, somewhat hirsute on the outside.

Culture.—This plant may be increased by sowing the seeds either in the autumn or early spring in the places where they are to remain, or in beds, to be removed in the beginning of the summer to the borders or clumps of the pleasure-grounds.

They afford variety among other plants of similar growth in these situations.

PEPPER. See PIPER.

PEPPER, GUINEA. See CAPSICUM.

PEPPER, JAMAICA. See MYRTUS.

PEPPERMINT. See MENTHA.

PERENNIAL PLANTS, are such as are of long duration. Such plants as are perpetuated by the roots, whether the leaves and stalks decay annually in winter, or always remain, provided the roots are of many years duration, are perennial. All plants, therefore, with abiding roots, both of the herbaceous, shrub, and tree kinds, are perennials; though in the general acceptance of the word perennial, it is most commonly applied to herbaceous vegetables with durable roots, more especially those of the flowery kind, which among gardeners are commonly called simply perennials, particularly the fibrous-rooted tribe: but it is equally applicable to fibrous, tuberous, and bulbous-rooted plants, whose roots are of several years' duration: likewise all shrubs and trees of every denomination, as having abiding roots, are perennial plants.

And these sorts of plants consist both of deciduous and ever-green kinds; those that cast

their leaves, &c. in winter being termed deciduous perennials, and those which retain their leaves, ever-greens.

The herbaceous perennials, of the fibrous, tuberous, and bulbous-rooted kinds, for the greater part have annual stalks, rising in spring and decaying in winter; and a great many lose their leaves entirely also in that season, such as the perennial sun-flower, asters, and numerous other sorts; and many retain their leaves all the year, but not their stalks; as is exemplified in the auricula, polyanthus, some campanulas, pinks, carnations, and many other plants.

Numbers of the herbaceous perennials multiply exceedingly by off-sets of the root, by which they are readily propagated. See OFF-SET, &c.

All the tree and shrub perennials are durable in root, stem, and branch; but renew their leaves annually. Even the ever-green kinds, although they are in leaf the year round, put forth new leaves every year, to which the old ones gradually give place. See DECIDUOUS and EVER-GREEN TREES, &c.

PERILOCA, a genus comprising plants of the woody climbing kind.

It belongs to the class and order *Pentandria Digynia*, and ranks in the natural order of *Contortæ*.

The characters are: that the calyx is a five-cleft perianthium, very small, segments ovate; permanent: the corolla one-petalled, wheel-shaped, five-parted: segments oblong, linear, truncated, emarginate: nectary very small, five-cleft, surrounding the genitals, putting out five threads, curved inwards, shorter than the corolla, and alternate with it: the stamina have short filaments, curved inwards, converging, villose: anthers twin, acuminate, converging over the stigma; with lateral cells: pollen bags five, at the notches of the stigma, each common to two anthers: the pistillum consists of two ovate germs, approximating: styles united at top: stigma capitate, convex, five-cornered, with the corners notched: the pericarpium consists of two large follicles, oblong, ventricose, one-celled, one-valved, glued together at the tip: the seeds very many, imbricated, crowned with a down: the receptacle longitudinal, filiform.

The species cultivated are: 1. *P. Græca*, Common Virginian Silk or Periploca; 2. *P. Secamone*, Green Periploca; 3. *P. Indica*, Indian Periploca; 4. *P. Africana*, African Periploca.

The first has the stems shrubby, twining round any support more than forty feet in height, covered with a dark bark, and sending out slender branches which twine round each other: the leaves are ovate-lanceolate, near four inches long,

and two broad in the middle, of a lucid green on their upper side, but pale on their under, opposite, on short footstalks: the flowers come out towards the ends of the small branches in bunches, and are of a purple colour. It is a native of Syria, flowering in July and August, but rarely ripening seeds in this climate.

It is sometimes called *Climbing Dog's-Bane*.

The second species has a twining, shrubby, even stem: the leaves are opposite, petioled, even, underneath paler, veined transversely: the panicles axillary, alternate, dichotomous, shorter than the leaves: the flowers are small. It differs obviously from the first sort in its small copious flowers. It is said to be a native of Egypt; but its place of growth is uncertain; flowering in July.

The third has many slender stalks, which twine about each other, and by a shrub or other support will rise near three feet high, putting out several small side-branches; these are hairy, as are also the leaves; which are about three quarters of an inch long, and half an inch broad, standing by pairs upon very short footstalks: the flowers come out in small bunches from the side of the stalks; are small, of a dull purple colour, and have a sweet scent. It flowers in the summer, but does not produce seeds in this climate. It is a native of the Cape.

There is a variety with smooth leaves and stalks, which comes from the same place.

Culture.—These plants may be easily increased by layers made from the young wood in the early spring or summer season. When they are fully rooted, they may be taken off and planted out, the first or hardy kind, either where they are to remain, or in the nursery, to be afterwards removed; and the two last, or tender sorts, into pots, to be protected during the winter.

The first sort likewise often succeeds by cuttings, and also the two last by the use of the hot-bed.

They may all be increased also by sowing the seeds procured from abroad in pots of light earth, plunging them in the hot-bed.

They should all be placed near support, to prevent their trailing upon the ground and fastening about other plants.

Where the two last sorts are kept constantly plunged in the tan-bed of the stove, they thrive and flower much better than in any other situation; but they should not be kept too warm in winter; and in the summer they should have a large share of free air admitted to them; for when they are kept too close their leaves will be covered with insects, and the plants become sickly in a short time.

The first sorts only require a little protection

in the winter. They all afford variety among potted plants.

PERIWINKLE. See VINCA.

PEROLA. See MOMORDICA.

PERSEA. See LAURUS.

PERSIAN LILY. See FRITILLARIA.

PERSICA. See AMYGDALUS.

PERSICARIA. See POLYGONUM.

PERUVIAN MASTICK TREE. See SCHTUNUS.

PETIVERIA, a genus containing plants of the woody exotic perennial evergreen kind for the stove.

It belongs to the class and order *Hexandria Tetragynia* (*Heptandria Monogynia*), and ranks in the natural order of *Holotaceae*.

The characters are: that the calyx is a four-leaved perianthium: leaflets linear, blunt, equal, spreading, permanent: there is no corolla (except the coloured calyx): the stamina have six or eight unequal, awl-shaped, converging filaments: anthers erect, linear-sagittate, bifid at top: the pistillum is an ovate germ, compressed, emarginate: style very short, lateral, in the groove of the germ: styles four, permanent, finally bent outwards, spinescent: stigma pencil-shaped: there is no pericarpium, except the crust over the seed: the seed single, oblong, narrower below, roundish, compressed, emarginate; with four barbed hooks, bent back outwards, rigid, acute, the middle ones longer (naked, but armed above with reflex spines).

The species are: 1. *P. alliacea*, Common Guinea-Hen Weed; 2. *P. octandra*, Dwarf Guinea-Hen Weed.

The first has a strong root, striking deep into the ground: the stems from two to three feet high, jointed, and becoming woody at bottom: the leaves oblong, three inches long and an inch and half broad, of a deep green and veined, placed alternately on short footstalks: the flowers are produced in slender spikes at the ends of the branches; are very small, and make no figure. It is common in the West Indies, flowering here in June.

It thrives most in a dry gravelly soil and a shady situation.

The second species differs from the first, in having a shorter and narrower stalk; and in the flowers having eight stamens; and, according to Linnaeus, the leaves are more rigid and quite smooth, the filaments purple and not white. It is a native of the West Indies.

Culture.—These plants may be increased by slips or cuttings planted out in the summer, as well as by seeds; which must be sown on a hot-bed early in the spring. When the plants are

come up, they should be removed into separate pots, and plunged into a moderate hot-bed. When the plants have obtained a good share of strength, they should be inured by degrees to the open air, into which they may be removed towards the end of June, placing them in a warm situation, where they may remain till autumn, when they must be placed in the stove, and during winter have a moderate degree of warmth.

They afford variety, and produce a good effect among other potted plants.

PETOLA. See MOMORDICA.

PETREA, a genus containing a plant of the climbing exotic shrubby kind for the stove.

It belongs to the class and order *Didynamia Angiospermia*, and ranks in the natural order of *Personatae*.

The characters are: that the calyx is a one-leaved, bell-shaped perianthium: border five-parted, spreading, very large, coloured, permanent: segments oblong, blunt, closed at the throat by five doubled, truncated scales; the corolla one-petalled, wheel-shaped, unequal, less than the calyx: tube very short: border flat, five-cleft: segments rounded, almost equal, spreading very much; the middle one larger and of a different colour: the stamens have four filaments, concealed within the tube of the corolla, ascending, two shorter: anthers oval, erect: the pistillum is an ovate germ: style simple, the length of the stamens: stigma blunt: the pericarpium is a capsule obovate, flat at top, two-celled, concealed at the bottom of the calyx: the seed single, fleshy.

The species is *P. volubilis*, Twining Petrea.

This rises with a woody stalk to the height of fifteen or sixteen feet, covered with a light-gray bark, and sending out several long branches, having a whiter bark than the stem: the leaves are at each joint, on the lower part of the branches placed by threes, but higher up by pairs; are five inches long, and two inches and a half broad in the middle, drawing to a point at each end; stiff, and their surface is rough, of a light green, having a strong dark midrib, with several transverse veins running to the borders, which are entire: the flowers are produced at the ends of the branches in loose bunches, nine or ten inches long; each flower upon a slender pedicel about an inch in length, of a fine blue colour.

There is a variety with bright blue petals.

Culture.—This is increased by seeds, which must be obtained from the places where the trees grow naturally, and be sown in pots plunged in a good hot-bed; and when the plants come up, they should be each planted in a sepa-

rate small pot filled with light loamy earth, and replunged into a hot-bed of tanner's bark, and be afterwards placed in the bark-bed in the stove, where they must constantly remain, and be treated like other plants of the same country.

They afford ornament in stove collections.

PETTY WHIN. See GENISTA.

PHASEOLUS, a genus containing plants of the climbing esculent and flowering kinds.

It belongs to the class and order *Diadelphica Decandria*, and ranks in the natural order of *Papilionaceae* or *Leguminosae*.

The characters are: that the calyx is a one-leaved, two-lipped perianthium: upper lip emarginate; lower three-toothed: the corolla papilionaceous: banner heart-shaped, blunt, emarginate, reclined; the side bent back: wings ovate, the length of the banner, placed on long claws: keel narrow, rolled spirally contrary to the sun: the stamens have diadelphous filaments, (simple and nine-cleft,) within the keel, spiral: anthers ten, simple: the pistillum is an oblong germ, compressed, villose: style filiform, bent in spirally, pubescent above: stigma blunt, thickish, villose: the pericarpium is a legume long, straight, coriaceous, blunt with a point: the seeds kidney-form, oblong, compressed.

The species is *P. vulgaris*, Common Kidney-Bean.

Other species may be cultivated for the purpose of variety as flower-plants.

It has the stem more or less twining, but in some of the cultivated dwarf varieties scarcely at all so, quite simple or unbranched: the leaves ternate, acuminate, rounded at the base, rough, on long petioles: the flowers axillary, in twin racemes, or else on twin petioles: corolla white, yellow, purple or red: the banner has a callus, but a small one, and placed near the edge above the claw: there is a white nectariferous scale between the claw of the banner and the single stamen, bent upwards, and growing to the filament: besides this, an obliquely bell-shaped, pellucid, striated nectary surrounds the pedicel of the germ within the connate filament; the size differs in the several varieties: the legume oblong, swelling a little at the seeds, when ripe one-celled: the seeds several, ovate or oblong kidney-shaped, smooth and shining; varying much in shape and size, but particularly in colour; being white, black, blue, red, and variously spotted. It is annual, and a native of both the Indies.

They were formerly called *Sperage Beans*, *French Beans*, &c.

The principal sub-varieties of the dwarf, or low-growing sorts, are: the early white dwarf,

the early speckled dwarf; the early yellow; the early liver-coloured; the early dun-coloured dwarf; the larger white or cream-coloured dwarf; the larger black and white speckled dwarf; the black-streaked dwarf; the red speckled dwarf; the speckled amber dwarf; the sparrow-egg dwarf; the Canterbury white dwarf; the Battersea white dwarf; the China speckled dwarf, consisting of black and white speckled, brown and white, red and white, &c. These are of upright dwarf bushy growth, rarely exceeding fifteen or eighteen inches in height; and seldom throw out runners, except the Canterbury and Battersea sorts, which sometimes send out a few stragglers, but which seldom extend to much distance.

The first three or four sorts are at present in most esteem for their coming early into bearing: being of smaller growth than the other sorts, they sooner form themselves for blossom and bearing, of course are proper for planting for the earliest crops, and for forcing in hot-beds, &c. As they, however, do not continue long in bearing, they are not so proper for the main crops as the larger dwarf sorts; particularly the black and white speckled, the Canterbury and Battersea kinds, which are all excellent bearers; but the two latter most of all, and the pods are smaller, more numerous, and esteemed the sweetest eating of all the dwarf kinds whilst young, though the pods of the large white dwarf, and the speckled kind in particular, continue exceedingly good, even when of pretty large size, but superior in the latter, both in a more plentiful longer production, and goodness for eating, being excellent for a principal crop in a family garden; as are also the Battersea and Canterbury sorts, which should not be omitted on the same occasion; and these two varieties are in most esteem for general culture by the market-gardeners, for main crops, as being by them considered both the most profitable in bearing, and having a smaller pod, the most saleable in the markets: however, any of the other dwarf sorts are also proper to cultivate occasionally, for variety, both for private and public use.

There is a scarlet bean which is by some considered a distinct species, but probably a variety of this, the running or twining stalks of which, if properly supported, rise to the height of twelve or fourteen feet: the leaves are smaller than those of the common garden-bean: the flowers grow in large spikes, are much bigger, and of a deep scarlet colour: the pods are large and rough; and the seeds are purple marked with black, sometimes pure white.

The principal subvarieties of these are: the

large scarlet climber, which rises with many twining runners upon support, eight or ten to twelve or fifteen feet high, having numerous large clusters of scarlet flowers, succeeded by large, thick, rough, fleshy seed-pods, containing large, thick, purplish beans.

The large white climber; having large clusters of white flowers, large, thick, rough seed-pods, and white seed. These sorts are alike in respect to their growth, differing only in the colour of their flowers and seed, which is pretty permanent: they are great bearers; and the plants of the same crop continue in bearing from July or August until October; the pods, even when large, boiling exceedingly green, being remarkably tender and well flavoured.

The large Dutch climber, which rises with twining runners, upon support, ten or twelve feet high; numerous clusters of white flowers, succeeded by long, broad, compressed-flat, smooth pods, containing large, oblong, flat, white seed: this is also a very great bearer, but it does not continue near so long in production as the two former climbers; its pods, however, which are very long, smooth, and fleshy, boil exceedingly green, tender, and good: and, of the runner kind, it is a very desirable family bean, inferior to none for sweetness of flavour.

But the following sorts are of a more moderate growth. The negro runner: the Battersea white runner: and, the Canterbury runner; which, though climbers, ramble less, but bear plentifully and continue some time. The pods are smaller, but very tender, very delicate in eating, while in moderate young growth.

Culture.—As these are all plants of the annual tender tribe, they require to be raised every year, in the latter spring and summer months, as from April till June or later, by different sowings, at the distance of a few weeks, when the danger of frosts is over.

Culture in the Dwarf Kinds.—In cultivating these sorts, proper kinds should be chosen for the different crops. As for the forward ones, any of the early sorts are proper, but the early white, early speckled, dun, and yellow kinds are rather the earliest bearers; and for the main crops any of the larger dwarf kinds, though preference should be given to the speckled, the Battersea, and the Canterbury dwarf kinds, as being all plentiful bearers, and continuing long in successional bearing on the same plants.

These sorts of beans, from their tender nature, seldom admit of being sown or planted earlier than April, when the weather is become a little settled; as the seed is not only impatient of cold moisture in the ground, and very subject

to rot, but the young plants that happen to come up early are often cut off, or greatly injured, by the morning frosts, or cold cutting winds, that frequently prevail in the beginning of this and the following month. But towards the middle of it, if the weather is fine and dry, some may be ventured in a warm dry situation and light soil, for the early natural crops; and in the latter end of it, or beginning of the following month, when the weather is suitable, it is proper to begin to put in the first general crops in the open quarters, &c., and to continue planting some every fortnight or three weeks until the middle or latter end of July; by which means regular supplies of young kidney-beans may be had for the table or market, from about the middle or latter end of June until the beginning of the autumn season.

Where, however, it is desired to try them as early as possible in the full ground, some may be put in about the beginning of April, in dry weather, close under a warm wall, or other similar situation where the soil is dry; and in a fortnight after some more, in a larger portion. If the first should fail, these sometimes succeed; and if both are attended with success, one will follow the other in bearing; though it is two to one against the success of the first planting. But as only a few should be planted so early, if they fail, it is only the loss of a little labour and seed, as the same ground will do again; and if they succeed and produce only a few but a week sooner than common, they will be esteemed a rarity, either for family use or the market.

They all succeed in any common dry soil of the garden; but for the forward crops, a dry light soil should constantly be chosen, rejecting heavy and wet grounds, for in such a soil most of the early-planted seed infallibly rot. Likewise for the early crops, it is highly requisite to have a sheltered warm situation full to the sun; a warm south border is a very proper exposure; but for the main crops, any of the open quarters may be made use of with propriety.

The methods of sowing or planting all the sorts is in shallow drills, from two to three feet asunder, to remain where sown.

For the early crops, taking advantage of a dry day, neat drills should be drawn with a hoe from north to south, two feet or thirty inches asunder, and near an inch deep; and to afford a greater chance of success, a drill may be made close along under the wall, where practicable; in these drills the beans should be dropped in rows along the bottoms, only about an inch and a half asunder, as many of this early sowing may fail; covering them evenly with the earth,

not more than an inch deep; as when covered too deep at an early period many are apt to rot, by the cold moist dampness of the earth. As soon as they are covered in, the surface should be lightly raked smooth; when the work is finished. They come up in about twelve days or a fortnight; when they should be managed as directed below; and the plants mostly come into bearing in six or eight weeks afterwards.

For the main crops to be planted afterwards, almost any situation, either in the borders, or an open exposure, may be employed; though an open situation in any of the large quarters is, as has been seen, the most proper. In this case drills should be drawn two feet and a half asunder, and about one inch deep; or, when it is designed to plant rows of savoys or cabbage-plants between, (as is often practised where necessary to husband the ground to the best advantage, but which should always be avoided if possible,) the drills should be a yard asunder at least; the beans being dropped in singly along the bottom of each drill, about two or three inches asunder, covering them in evenly afterwards with the earth about an inch deep, and finishing with a light raking to smooth the surface. They mostly come up at this season in ten or twelve days, and sometimes sooner in fine weather; and the plants usually come into plentiful bearing in six or eight weeks afterwards.

In planting out the later general crops, when the weather proves very dry and hot, and the ground of course very dry, it is proper either to soak the beans a few hours in soft water previous to planting; or, instead of this, letting the drills for the reception of the beans be well watered, and planting them immediately as above, covering them in the proper depth. Either of these methods is very advisable in dry weather in the heat of summer; it being necessary at such times to promote the free germination of the seed, in order to bring them up soon and regularly, as they would otherwise rise in a straggling manner.

In regard to the general Culture.—When the plants of all the above crops are come up, they are in general to remain where sown or planted; to yield their produce; though when necessary some may be transplanted, keeping them clean from weeds by occasional hoeing in dry weather; and when the plants are advanced about three or four inches high, hoeing up a little earth to their stems on each side, which will forward their growth and promote their strength; continuing the care of destroying weeds as often as their growth may render it necessary; which is principally all the culture required for these sorts, in the full ground, till they arrive at a bearing state, and

their produce is fit to gather; except to the earliest crops on warm sunny borders, in very dry hot weather, when it may be beneficial to give occasional waterings to the plants in the mornings or evenings, especially when in blossom, and fruiting.

In gathering the produce of these sorts of beans, it should always be performed when the pods are quite young, or at least before they become large, and the beans in them attain any considerable size, as they are then tough, stringy, and rank tasted; and in order to continue the plants in bearing as long as possible, the gatherings should be regularly repeated two or three times a week; for by gathering the pods often and clean, as they become fit, the plants blossom more abundantly, and continue fruiting more plentifully and for a much longer period.

Large quantities of these dwarf kinds are often cultivated in the gardens and fields in the neighbourhood of large towns, for supplying the markets during the latter part of the summer season.

Culture of early Crops by artificial Heat.—In order to have these sorts of beans as early as possible, recourse is had to raising them by the aid of heat, in two or three different methods, as by raising the plants in a hot-bed, an inch or two high, and then planting them out into a warm border, by raising and continuing the plants in a hot-bed so as to bear their crops, and by aid of a hot-house.

In the first of these methods, they may be forwarded a fortnight earlier than those sown entirely in the full-ground; for this purpose, towards the latter end of March, or early in the following month, a moderate hot-bed should be prepared a foot and a half or two feet in depth of dung, covered either with a frame or hand glasses, or arched over with hoops or rods, to be covered with mats; earthing the bed with fine, light, rich mould, six inches deep; then having some seed of the early sorts, it should be sown pretty close either all over the surface, an inch or two apart, covering them with earth about half an inch deep, or in small close drills, earthing them over the same depth; or where only a few are wanted, they may be sown in large pots at about an inch distance and half a one deep, and the pots plunged into a hot-bed, or placed in a hot-house; and when the plants come up, the pots be removed by degrees into the full air in warm days, to harden the plants for transplantation; and it is a good method to plant a quantity of beans in small pots (thirty-twos or forty-eights), three in each pot, plunging the pots in a hot-bed; and when the plants

are fit for being transplanted out, they can be readily turned out of the pots with the whole ball of earth about their roots, so as not to feel their removal. But in raising the plants in either of these methods with this view, attention is particularly necessary to inure them gradually to the full air, by taking off the covers of the glasses or mats in all mild weather from those in hot-beds, and only covering them in cold nights; or the pots in the hot-house should be placed abroad in fine days; but as they advance in growth, and the weather becomes warmer, they must be exposed by degrees to the full air, day and night, to harden them properly, previously to their being finally transplanted out. They should also be allowed frequent moderate refreshments of water.

When they have shot out their proper leaves an inch or two broad, and all danger of frosty mornings and other bad weather is apparently over, proceed to plant them out into a warm border, under a wall or other fence, taking them up with their roots as entire as possible, and with as much earth as will hang about them, or with a small ball of earth; and those raised in small pots by threes may also be easily turned out with the whole ball of earth entire; and as to the mode of planting them, those which cannot readily be taken up with balls may be planted by dibble, in a row along close under a south wall, or some in cross rows two feet asunder, forming shallow drills for their reception, in which the plants should be set three or four inches apart; but those with good balls about their roots should be holed in with a trowel; and if some of those for a small early production are also disposed in patches, three plants in each, so as to be covered occasionally in cold nights with hand-glasses, it will be found very beneficial in forwarding their growth. As soon as they are planted, in either method, a moderate watering should be given to settle the earth close about the roots, and repeated in dry weather as there may be occasion, till the plants have taken fresh root in their new situations.

After this they should be kept clean from weeds; and when they are a little advanced in growth, some earth drawn lightly up about their stems; and as the warm season advances, if it prove hot and dry, refreshments of water will greatly forward and strengthen the growth of the plants and forward their perfection.

In the second method—about the beginning or towards the middle of February a dung hot-bed should be made, either a small one in which to sow the beans thick for being transplanted, when the plants are about an inch high, into a larger

hot-bed, to remain for bearing; or a large one at first, in which to sow the seed and continue the plants to attain perfection, as for one, two, or more three-light frames, about two feet and a half high in dung: and when the great heat and steam are a little abated, the bed should be covered with light, rich, dry mould, six or eight inches thick, for the reception of the seed; then small drills should be drawn from the back to the front of the bed, near an inch deep, and about fifteen or eighteen inches asunder; placing the beans two or three inches apart, and covering them evenly with the earth the above depth, then putting on the lights, tilting them behind an inch or two high daily, to give vent to the steam; and when the plants appear, continuing every day to admit air to them at all opportunities, in proportion to the temperature of the weather and heat of the bed, to prevent their drawing up weak, and promote their strength as they rise in height; bestowing also at this time moderate refreshments of water in sunny days; and when they are two or three inches high, applying a little earth to their shanks; likewise supporting a moderate heat in the bed during the cold weather, by occasional linings of hot dung: and accordingly as the plants advance in growth, and the warm season increases, augmenting gradually the portion of fresh air daily to harden them by degrees, so as almost to be fully exposed occasionally in very warm days, especially when beginning to blossom; but keeping them close on nights; continuing also the care of frequent light waterings, which must be increased in quantity as the plants advance in size, particularly when they are in blossom and in a fruiting state: in their advanced growth, if they press much against the glasses of the frame, it is proper to raise it at bottom two or three inches, to give room at top for their free growth, which is necessary to promote a plentiful bloom for furnishing a sufficiently full crop of beans.

In this mode they may be had at as early a period as possible, as in April or early in May; but to have a constant succession of early kidney-beans till crops in the natural-ground come in, another crop should be brought forward in hot-beds, as above, in three weeks after the first hot-bed is made up.

Where frames cannot be afforded for the above purpose, it may be effected in March with occasional coverings of mats; a hot-bed being made about two feet high of dung, earthing it directly six or seven inches thick, sowing the beans as directed above, then arching the bed over with hoops, &c., and covering it every night, and in all bad weather, with mats; but

admitting the free air every mild day, gradually hardening the plants as they acquire strength, and giving occasional waterings.

In the third method—early kidney-beans may be obtained with very little trouble at almost any time in winter or spring, by raising them in pots, or long narrow trough-like boxes, about two or three feet long and eight or ten inches broad at top, placing them any where in the lower part of the hot-house; when the plants will succeed.

The proper kinds for this purpose are: the early white, yellow, and dun-coloured dwarfs, the latter being rather a preferable bearer, continuing in longer production; and the speckled dwarf also succeeds very well, and continues long in bearing in this mode of culture.

In respect to the method of management in these cases, any time in winter or early in spring, some large pots (sixteens or twenty-fours) or boxes may be filled with light rich earth, and placed in the hot-house, some being arranged upon the top of the surrounding wall of the bark-bed, and on the top of the front flues towards the upright glasses, and in other similar convenient situations as room may admit, planting in each pot four beans, near an inch deep; or, if boxes, along the middle, in a sort of double row, triangular-ways, about four inches asunder, and the above depth: they soon germinate, and in a few days appear above ground: when they begin to sprout, it is proper to moisten the mould with a little water, which facilitates the protrusion of the plants out of the earth.

Their after-culture is very easy:—when they are come up, frequent waterings should be given, as three times a week, as the earth dries very fast. It should always be kept moderately moist, in order that the plants may blossom freely and produce a plentiful crop, which is often in as great perfection as in the full-ground.

As in the other crops, they should be gathered often; as it is the way to continue the plants long in a bearing state.

A regular succession of early young crops of these beans may be obtained in this way two or three months, by repeated sowings at the interval of about three weeks, so as to have young plants advancing in pots or boxes in two or three different degrees of growth succeeding each other.

Where there is not much stove-room, it may be proper to plant the beans for succession crops in small pots (forty-eights), three beans in each; and as these take up but little room, they may be stowed any where close together, or between the other larger pots: the plants will come up

and be advancing in growth, so as that when those of the preceding crops are going off, these may be readily turned out of the small pots with the whole ball of earth about their roots, and replanted into large pots, &c. to remain for fruiting, giving water at planting, and frequently afterwards, as above, in the first crop: by this practice a month's growth in the plants may be gained, and a constant succession of beans for the table be had.

Culture in the Climbing Kinds.—These are raised from the seed, by sowing it annually in the later spring and summer months, as in the dwarf sorts. For this purpose the scarlet runner and the white sub-variety of it are the most proper for the general crops, as being not only very great bearers and continuing in perfection two or three months, but from their pods, when even pretty large, remaining green, fleshy, tender, and well flavoured. Some of the Dutch runners, and any of the other climbers, may also be cultivated with advantage.

The most proper season to begin planting the main crops of all those sorts is the first or second week in May, if the weather be fine; as being of a delicate nature like the dwarfs, when planted earlier, both the seed and plants are subject to danger from the same causes: however, in a south border, or some similar warm situation and dry soil, a few may be planted in the middle or towards the latter end of April, to take their chance; but for the general crops, the most successful season for planting is from the above period until the middle or latter end of June, but not later than the beginning of July: but where the scarlet kind and variety are planted principally, one planting in May or beginning of June will come into bearing in July or August; and when the pods are kept gathered clean, according as they are fit for use, the plants continue shooting, blossoming, and bearing abundantly until the end of September, and often until the end of October, or even till destroyed by the cold and frosts: but two plantings of any of the sorts of runners, one in May and the other in June, or early in July, are amply sufficient to furnish a very abundant supply for the whole season of this sort of crop.

All these kinds prosper almost any where in the garden, both in close and open situations; choosing principally a lightish soil, especially for the forward crops: and the richer the ground, the better it is for the purpose.

As all the running kinds require support of some kind or other to climb upon, they should be planted either in wide rows, for the convenience of placing tall sticks or poles along each

row for the runners of the plants to wind themselves round for support, or be planted against some sort of fence or treillage work for the same purpose of training up and supporting the runners. When, however, it is designed to train them upon sticks or poles, drills should be drawn four feet or four and a half asunder, especially for the larger kinds, and an inch deep, in which the beans should be dropped three or four inches apart; covering them in evenly with earth, and raking the surface smooth. The beans will sprout in a few days, and come up in less than a fortnight.

When the plants are three or four inches high, a little earth should be drawn with a hoe up to their stems, to strengthen them, and encourage them to send forth strong runners. At this time also all weeds between the rows should be cut up and be removed.

As soon as they begin to push forth their runners, some tall sticks or poles should be placed for them to ascend upon; and as they are placed, conducting the runners towards them, in a direction according to their natural mode of climbing, which is generally to the right, or contrary to the sun's motion: they will thus naturally encircle the sticks or poles, and ascend to their tops, even if ten or fifteen feet high, producing blossoms and fruit from bottom to top.

When it is intended to plant these sorts against fences for support, it should be done in a row close along to the fence; and if against a wall or paling, either placing tall poles, or drawing some strong packthreads from top to bottom at six inches distance; the plants readily twining round them, and supporting themselves to a great height.

In gathering the produce of all these kinds, the same circumstances should be attended to as in the dwarfs—to gather the pods whilst young and tender; and to continue the plants long in full bearing, always gathering the pods clean as they become of a proper size: and they will continue fruiting more abundantly and in better perfection.

When it is intended to cultivate any of these climbing beans as flowering-plants, the scarlet kind and its variety are the best sorts for the purpose. They should be sown as above in any of the compartments of the pleasure-garden, in patches, alternately scarlet and white sort, two or three beans in each patch, about an inch deep; and when the plants are up and begin to push forth runners, tall poles or branchy sticks should be placed for them to climb upon: they will thus effect a very fine variety all summer, until the autumn.

These kinds of beans are also often employed to run over arbours, and to twine round lines, from the top of tall stakes, and stems of small trees; also to run up along the sides of houses, or against walls, either upon poles, or upon packthread-strings, suspended from above, about which they will twine themselves many feet high, bearing abundance of flowers and fruit: they are likewise sometimes trained to form shady walks, by means of sticks or poles arranged along each side, or by support of a sort of treillage-work, ranging some tall stakes five or six feet asunder, railing them along the top with poles, or pan-tile laths, or extending strong packthread lines; and from either of which suspending strings to the ground, six or eight inches asunder, fastening them down with pegs: upon these strings the plants will climb, and form a close hedge; or they might be occasionally arched over the top in a similar manner, for the runners to extend, and form a vaulted roof and complete shade. Thus this fine climber may be trained in various ways according to fancy, both for use and ornament; from which those not accommodated with gardens may plant them in pots or boxes, to be placed in court-yards, windows, balconies, &c.

Saving Seed.—In order to have perfectly good seed, it is necessary to sow a sufficient quantity in rows on purpose, suffering the whole crop of the plants to remain without gathering any for use: by this means the seed ripens early, and in the highest perfection; which is essentially necessary for those who design the seed for public supply. In private gardens, and many others, they often, however, after having gathered the prime of the principal crops, leave the latter produce of them to grow for seed; which, although it may be tolerably good, is not always so large, plump, and fine, as in the former method.

When the seed is quite ripe, which is easily known by examining a few of the pods, the plants should be pulled up and spread loosely along in rows, or upon any low hedges, &c., turning them occasionally that the beans may dry and harden well; which when effected, either thrash them out directly, or lay them up in some dry loft or other room till convenient; and when thrashed out and cleared from the rubbish, spread them upon some clean airy floor, or some such place in the dry, to harden perfectly; then they should be put up in bags for next year's use:—some think the change of seed of this kind to be of much consequence.

PHILADELPHUS, a genus containing plants of the hardy deciduous flowering shrubby kind.

It belongs to the class and order *Icosandria*

Monogynia, and ranks in the natural order of *Hesperideæ*.

The characters are: that the calyx is a one-leaved perianthium, four- or five-parted, acuminate, permanent: the corolla has four or five roundish petals, flat, large, spreading: the stamina have twenty or twenty-five awl-shaped filaments, the length of the calyx: anthers erect, four-grooved: the pistillum is an inferior germ: style filiform, four- or five-parted: stigmas simple: the pericarpium is an ovate capsule, acuminate at both ends, naked at the top by the calyx being barked, four- or five-celled: partitions contrary: the seeds numerous, oblong, small, decumbent, arilled, fastened to the thickened edge of the partitions: arils club-shaped, acuminate, toothleted at the base.

The species is *P. coronarius*, Common Syringa or Mock Orange.

It is a shrub that sends up a great number of slender stalks from the root, seven or eight feet in height, having a gray bark, and putting forth several short branches from their sides: the leaves ovate or ovate-lanceolate; those upon the young shoots three inches and a half long, and two broad in the middle, terminating in acute points, and having several indentures on their edges; they are rough and of a deep green on their upper side, and pale on their under; stand opposite upon very short footstalks, and have the taste of fresh cucumbers: the flowers come out from the side, and at the end of the branches, in loose bunches, each on a short pedicel; they are white, and have a strong scent, which at some distance resembles that of orange-flowers; but near, it is too powerful for most persons: the flowers appear at the end of May, and continue a great part of June. It is a native, probably, of the South of Europe.

There are two varieties: the dwarf syringa, which seldom rises above three feet high: the leaves are shorter, more ovate, and little indented on their edges: the flowers come out singly from the side of the branches, and have a double or treble row of petals of the same size and form as the other, and the flowers have the same scent; but flowering very rarely, it is not so much in estimation.

The Carolina syringa, which rises with a shrubby stalk about sixteen feet high, sending out slender branches from the sides, opposite to each other: the leaves smooth, shaped like those of the pear-tree, entire, opposite, on pretty long footstalks: the flowers are produced at the ends of the branches; they are large, but without scent; each has four white oval petals spreading open, and a large calyx composed of four acute-pointed leaflets.

Polemonium coeruleum
 2 Blue Greek-Valerian

Culture.—These plants may be increased by suckers, layers, and cuttings.

The suckers are sent from the roots in great plenty; these should be taken from the old plants in autumn, and be planted in a nursery, to grow one or two years till they have obtained sufficient strength, when they may be removed to the places where they are to remain.

The layers may be laid down in the autumn, being made from the young twigs. These may be taken off in the following autumn, when well rooted, being planted out where they are to remain.

The cuttings of the young shoots may be planted in the autumn, in a shady situation, where they soon form plants.

The plants are extremely hardy, and thrive in almost any soil or situation, but grow taller in light good ground than in that which is stiff.

They are commonly disposed in plantations of flowering shrubs, among others of the same growth; mixing very well with lilacs, gelder roses, and laburnums; and particularly valuable from their thriving under the shade of trees, and forming a blockade against low buildings, where persons have no objection to their strong smell.

PHILLYREA, a genus containing plants of the hardy evergreen shrubby kind.

It belongs to the class and order *Diandria Monogynia*, and ranks in the natural order of *Sepiariae*.

The characters are: that the calyx is a one-leaved perianthium, tubular, four-toothed, very small, permanent: the corolla one-petalled, funnel-form: tube scarcely any: border four-parted, revolute, acute; segments ovate: the stamina have two filaments, opposite, short: anthers simple, erect: the pistillum is a superior roundish germ: style simple, the length of the stamens: stigma thickish: the pericarpium is an ovate-globular, two-celled berry: the seeds solitary, flattish on one side, convex on the other, one of them frequently abortive.

The species are: 1. *P. media*, Lance-leaved Phillyrea; 2. *P. angustifolia*, Narrow-leaved Phillyrea; 3. *P. latifolia*, Broad-leaved Phillyrea.

The first rises to an equal height with the third or true sort, but the branches are more diffused, and have a darker bark: the leaves are of a darker green, are more than two inches long, and almost an inch and half broad, a little serrate on their edges, opposite on short footstalks: the flowers axillary, in long bunches, of an herbaceous white colour.

There are several varieties: namely, the privet-leaved and olive-leaved; which are of humbler

growth, seldom more than eight or ten feet high: the branches of the first are weaker, and spread wider, and are covered with a light brown bark: the leaves are stiff, almost two inches long, and half an inch broad in the middle, drawing to a point at both ends, and sit close to the branches: the flowers are in little axillary clusters, small and whiter. In the latter the branches are stronger, and spread out wider; the bark is of a lighter colour: the leaves are stiff, smooth, and entire, on very short footstalks, of a lucid green, and terminating in a point: the flowers in clusters, on pretty long peduncles, from the axils of the young branches, small and white. And in the Kew catalogue there are three other varieties mentioned: namely, the long-branched, which has long upright branches; the drooping, which has the branches hanging down and straddling; and the box-leaved.

The second species has the stalk ten or twelve feet high, sending out opposite branches, covered with a brown bark spotted with white: the leaves are smooth, stiff, narrow, entire, sessile, about an inch and half long, and half an inch broad in the middle, drawing to a point at both ends, of a light green, and pointing upwards: the flowers come out in large clusters at each joint of the branches, sitting close like whorled flowers, and almost surrounding them; they are small and white.

There is a variety termed rosemary-leaved, which is of humbler growth, seldom rising more than four or five feet high, sending out slender, opposite, straight branches, sparsely disposed: the leaves dark green, stiff, and entire; about an inch long, and not more than an eighth of an inch broad, sessile: the flowers are small, white, in clusters from the side of the branches: the berries very small, rarely ripening in this climate. And in the Kew catalogue another variety is mentioned, under the name of Dwarf Phillyrea.

The third, True or Smooth Broad-leaved, rises with a strong upright stem to the height of eighteen or twenty feet, dividing into several branches, covered with a smooth grayish bark: the leaves are entire (or obscurely serrate), firm, of a light green, an inch and half long, and an inch broad, on short footstalks: the flowers are axillary, on each side, of an herbaceous white colour, in small clusters; they come out in March, but being small make no great appearance.

There is a variety, the prickly broad-leaved, which is as high as the smooth one, and sends out several strong branches, which grow erect, and are covered with a gray bark: the leaves are an inch and half long, and an inch broad, firm,

of a lucid green, and serrate, each serrature ending in a spine. And the Kew Catalogue has another, under the name of *Ilex-leaved*.

Culture.—These plants are capable of being increased either from seeds or layers, but the latter being the most expeditious method is chiefly preferred in this climate.

The best season for laying them down is in autumn, when the ground should be dug round the stems of the plants intended to be layed, rendering it very loose; then making choice of a smooth part of the shoot, a slit should be made in it upwards, in the manner practised in laying carnations, bending the branch gently down to the ground, making a hollow place to receive it; and having placed the part which was slit into the ground, so as that the slit may be open, it should be fastened down with a forked stick that it may remain steady, covering that part of the branch with earth about three inches thick, keeping the upper part erect. The layers must be kept clean from weeds in the spring and summer following, as if suffered to grow up amongst them, they will prevent their taking root.

In the autumn following most of the plants thus laid will be rooted, at which time they may be taken off, and carefully planted in a nursery, where they may be trained three or four years in the manner they are intended to grow; during which time the ground should be dug between the rows, and be cut about the roots of the plants every year, to cause them to strike out strong fibres, so as to support a good ball of earth when they are removed. Their stems should likewise be well supported with stakes, in order to make them straight, otherwise they are very apt to grow crooked and unsightly. When they have been thus managed three or four years, they may be removed into the places where they are designed to remain. The best time for this is the end of September, or the beginning of October, but in removing them, their roots should be dug round; and all downright or strong roots, which have shot out to a great distance, be cut off, that they may have balls of earth preserved to their roots, otherwise they are liable to miscarry: and when placed in their new situations, some mulch should be laid upon the surface of the ground to prevent its drying.

The plants should likewise be supported with stakes until they have taken fast hold of the earth, to prevent their being turned out of the ground, or displaced by the winds, which destroy the fibres that are newly put out, and greatly injure the plants.

They delight in a middling soil, which is

neither too wet and stiff nor too dry, though the latter is to be preferred to the former, provided it be fresh. The sorts with small leaves are commonly two years before they take root when layed; therefore they should not be disturbed, as the raising them out of the ground greatly retards their rooting.

In the seed method, the seeds should be sown in the autumn soon after they are ripe, as when they are kept out of the ground till spring they do not grow the first year. They succeed best when sown in pots or boxes filled with light loamy earth, and placed under a garden frame where they may be screened from hard frost, but always exposed to the open air in mild weather. If the seeds are sown early in the autumn, the plants appear in the spring; but if they should not come up, the pots should be plunged into the ground in an east border, where they may only have the morning sun, in which situation they should remain the following summer; during which time they may be constantly kept clean from weeds, and in the autumn removed again under a frame for shelter in winter, and the spring following the plants will certainly come up, if the seeds were good. Towards the middle of April, the pots should be again plunged into the ground on an east border, to prevent the air from drying the earth through the pots, which is generally the case when the pots stand upon the ground; so that they must then be frequently watered, which should not be practised to these plants where it can be avoided. In the autumn following the plants should be carefully taken out of the pots and planted out in a nursery-bed, covering the surface with old tan to keep out the frost; and if the winter prove severe, they should be covered with mats: afterwards they may be treated as those from layers.

These shrubs are so hardy as to thrive in the open air in this climate, and are never injured except the winters are very severe, which sometimes causes their leaves to fall, and kills a few of the weaker branches, but these are repaired by new shoots the following summer; so that there are few evergreen trees which are hardier, or that more deserve to be cultivated for the purposes of ornament.

The first and third sorts and varieties are very proper to intermix with other evergreens of the same growth, to form clumps in pleasure-grounds and parks, or to plant round the borders of woods which are filled with deciduous trees, where in the summer time their dark shades make a fine contrast with the brighter green leaves of the deciduous trees; and in winter, when the latter are destitute of leaves, they have a

fine effect. These may be trained up to stems, so as to be out of the reach of cattle, and be planted in open places, where, if they are fenced against cattle till they are grown up, they may be afterwards exposed. The others, which are of humbler growth, should be confined to gardens or other inclosures, where they may be secured from cattle, &c. They should only have the irregular branches pruned in, occasionally as they want it.

PHLOMIS, a genus containing plants of the shrubby and under-shrubby evergreen kinds.

It belongs to the class and order *Didynamia Gymnospermia*, and ranks in the natural order of *Verticillatæ* or *Labiatæ*.

The characters are: that the calyx is a one-leaved perianthium, tubular, oblong, five-cornered, toothed, permanent: involucre below the whorl: the corolla one-petalled, ringent: tube oblong: upper lip ovate, vaulted, incumbent, compressed, villous, obsoletely bifid: lower lip trifid: the middle segment larger, two-lobed, blunt; the side ones small, more acute: the stamina have four filaments, concealed under the upper lip, of which two are longer: anthers oblong: the pistillum is a four-parted germ: style the length and situation of the stamens: stigma bifid, acute; the lower cleft longer: there is no pericarpium: calyx containing the seeds at the bottom: the seeds four, oblong, three-sided.

The species are: 1. *P. fruticosa*, Shrubby Phlomis, or Jerusalem Sage; 2. *P. purpurea*, Sharp-leaved Purple Phlomis; 3. *P. Italica*, Blunt-leaved Purple Phlomis; 4. *P. Lychnitis*, Sage-leaved Phlomis; 5. *P. laciniata*, Jagged-leaved Phlomis; 6. *P. tuberosa*, Tuberous Phlomis; 7. *P. Zeylanica*, White Phlomis; 8. *P. nepetifolia*, Cat-mint-leaved Phlomis; 9. *P. leonurus*, Narrow-leaved Phlomis, or Lion's-Tail; 10. *P. Leonitis*, Dwarf Shrubby Phlomis.

The first has a pretty thick shrubby stalk, covered with a loose bark, rising five or six feet in height, and dividing into many irregular branches, which are four-cornered, woolly when young, and afterwards become woody: their joints are pretty far asunder; at each of these are placed two roundish leaves opposite, on short footstalks; they are woolly on their under side: the flowers come out in thick whorls round the stalks, and are yellow; they appear from June to August; but the seeds very rarely ripen in this climate. It grows naturally in Spain and Sicily.

There are two varieties: The Narrow-leaved shrubby Phlomis, or Jerusalem Sage, which does not rise so high as the above; the branches are weaker; the leaves longer, narrower and rounder; the whorls of flowers smaller, but the

flowers of the same shape and colour. These have been long cultivated under the title of French Sage, &c.

The Broad-leaved shrubby Phlomis, which has a shrubby stalk like the former, but much lower, seldom rising more than three feet and a half high, sending out branches on every side: the leaves hoary, broader than either of the former, of an oblong ovate form, on pretty long footstalks and whiter: the whorls large, with bigger flowers, the upper lip of which is very hairy.

The second species has the stem rather shrubby, erect, branched, slightly quadrangular, covered with thick wool, especially the younger branches: the leaves are opposite, ovate-oblong, obtuse, crenate, netted-veined, woolly on both sides, but most on the under one; the lowermost cut off at the base, but not heart-shaped, on long footstalks; the upper ones on shorter: the footstalks channelled, very woolly: the wool of the whole plant is formed like little stars: the whorls sessile in the axils of the upper leaves, consisting of six or eight flowers which are sessile, the same size with those of the first sort, but pale purple. It has a soapy smell, and is a native of Spain, flowering in June.

The third has the leaves less distinctly veined on the under side than in the second sort, and almost equally woolly on both sides, instead of being green on the upper; the lowermost are heart-shaped at the base: the bractes are blunt, by no means pungent; half as long as the calyx, which is also remarkably obtuse. It is a native of Italy and Portugal, flowering from June to August.

The fourth species has the habit of the first, but the leaves are narrower: the corolla is scarcely bigger than the calyx: the involucres linear, crinite with long hairs: the root is hard, thick, twisted: the leaves oblong, russet-coloured, cottony: the flowers of a golden colour, handsome, and very apparent: the bractes cordate, acuminate. It is a native of the South of France, &c., flowering from June to August.

The fifth has a perennial root: the stalk a foot and a half high which decays in the autumn, but the lower leaves continue all the year: the stem leaves are of the same shape with the lower, but smaller: the flowers in whorls: calyx downy: corolla of a dusky purple colour: they appear in June, but the seeds do not ripen in this climate. It was found in the Levant.

The sixth species has a tuberous root: the stalks are purple, four-cornered, five or six feet high: the leaves six inches long, three broad

at the base, terminating in acute points, deeply crenate on their edges: the flowers of a pale purple colour and hairy: they appear in June and July, and the seeds ripen in September; soon after which the stalks decay; but the roots abide many years. It is a native of Siberia.

The seventh species has the stem of the same stature with the ninth, two feet high, upright, herbaceous, four-cornered, blunt: the leaves sub-tomentose, marked with lines, petioled, remotely subserrate, longer than the internodes: the whorls sub-terminating with an awl-shaped involucre.

It is biennial, and a native of the East Indies, flowering from June to October.

The eighth has the stem simple, upright, quadrangular, blunt: the leaves deeply and somewhat bluntly serrate, green: the petioles the length of the leaves: the whorls few towards the top, globular, many-flowered: the calyx somewhat hairy, cylindrical, with a spiny and very sharp border, the upper tooth twice as large as the rest, and from four to six small teeth: the corolla villose, of the same appearance and colour with that of the ninth sort, but only one-third of the size; upper lip roundish, long, emarginate; lower short, trifid, even: involucre awl-shaped, reflex: filaments cohering in pairs: stigmas two, filiform, the upper shorter by half than the under. It is annual, and a native of the East Indies, flowering here in September and October.

The ninth species is a very handsome plant when it is in flower. It rises with a shrubby stalk seven or eight feet high, sending out several branches, which are four-cornered: the leaves are about three inches long, and half an inch broad, hairy on their upper side, and veined on their under: the branches have each two or three sessile whorls of flowers towards the ends: the corolla is of a tawny or golden colour, and shining like silk; upper lip long, tomentose, ciliate, quite entire; lower lip short, naked, membranaceous; the lateral segments reflex, dry, the intermediate one trifid, emarginate in the middle: the filaments snow-white: the anthers two-lobed, yellow, having globular meal sprinkled over them only at the base. It is a native of the Cape, flowering from October to December.

There is a variety of it with variegated leaves.

The tenth has the stalk shrubby, square, three feet high: branches four-cornered, in pairs: leaves rough on their upper side, veined, and pale green on their under: the corolla neither so long nor so deep coloured as in the ninth sort, to which it bears much resemblance, and is nearly allied; but the leaves are ovate, not lanceo-

late, and more tomentose: it differs materially from it by its awned calyxes: it agrees more with the eighth, but differs from it in having a shrubby stalk; small, blunt, more compact leaves; and the neck of the calyx rough-haired. It is a native of the Cape, flowering in June and July.

Culture.—All these plants may be increased by layers and cuttings.

The two first hardy sorts in particular grow freely by the first method: the young branches should be chosen, and laid in the common way, any time in autumn, spring, or summer; when they readily strike root, and commence proper plants by the autumn following, when they should be planted where they are to grow.

The cuttings should be made from the young shoots in spring and summer, being planted in a shady border, giving plenty of water in dry weather; when many of them will take root, and make good plants by the autumn following. The cuttings of the green-house kinds should, when made in the spring, be planted in pots, in order to be continued in shelter until May; or if the pots be plunged in a hot-bed, it will greatly forward their rooting; though, when the young shoots are planted in June or July, in a bed or border of rich earth, many of them take root, but may be much forwarded if covered down close with hand glasses, removing the glasses when the cuttings begin to shoot.

The fifth may likewise be increased by slips planted at the same time; and the sixth by offsets. The seventh should be preserved in the bark stove.

They are all very ornamental plants in the borders, green-house, and stove collections, according to the kinds.

PHLOX, a genus comprising plants of the herbaceous, fibrous-rooted, flowery, perennial kind.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Rotaceæ*.

The characters are: that the calyx is a one-leaved perianthium, cylindrical, ten-cornered, five-toothed, acute, permanent: the corolla one-petalled, salver-shaped: tube cylindrical, longer than the calyx, narrower below, curved in: border flat, five-parted: segments equal, blunt, shorter than the tube: the stamina have five filaments, within the tube of the corolla, two longer, one shorter: anthers in the throat of the corolla: the pistillum is a conical germ: style filiform, the length of the stamens: stigma trifid, acute: the pericarpium is an ovate capsule, three-cornered, three-celled, three-valved: the seeds solitary, ovate.

Painted by E. Edwards

London Published July 1st 1815, by G. Kneller Fleet Street

Engraved by F. Santen

1 *Phlox paniculata*
Panicled Lychnidea

2 *Polygala chamae-burus*
Box leaved Milkwort

3 *Physalis alkakengi*
Big Winter Cherry

The species are: 1. *P. paniculata*, Panicked Lychnidea; 2. *P. suaveolens*, White-flowered Lychnidea; 3. *P. maculata*, Spotted-stalked Lychnidea; 4. *P. pilosa*, Hairy-leaved Lychnidea; 5. *P. Carolina*, Carolina Lychnidea; 6. *P. glaberrima*, Smooth Lychnidea; 7. *P. divaricata*, Early-flowering Lychnidea.

The first has the stalk smooth, of a light green, about two feet high, sending out a few side branches: the leaves are near three inches long, and one broad in the middle, of a dark green, and sessile: the flowers in a terminating corymb, composed of many smaller bunches, which have each a distinct footstalk, and support a great number of flowers, which stand on short slender pedicels: the calyx short, cut almost to the bottom into five narrow acute segments: the corolla is pale purple, appearing late in July, and often followed by seeds which ripen in autumn. It is a native of North America, flowering in August and September.

The second species has white flowers, moderately sweet-scented. It is a native of North America, flowering in July and August.

The third has upright stalks, of a purplish colour, closely covered with white spots, and about three feet high: the leaves about three inches long, and one broad at their base, ending in acute points. Towards the upper part of the stalks are small branches opposite, each terminated by a small bunch of flowers; but on the top of the principal stalk is a long loose spike of flowers, composed of small bunches from the axils at each joint; each cluster having one common peduncle near an inch long, but the pedicels are short. The flowers are of a bright purple colour, and appear late in July: if the season be temperate, or the soil moist, they continue in beauty a great part of August, but rarely perfect seeds in this climate. It is a native of North America, flowering in August.

The fourth species has the stalks about a foot high: the leaves narrow-lanceolate, ending in acute points, sessile, a little hairy: the calyx cut into acute segments almost to the bottom: the tube of the corolla slender and pretty long, cut at top into five ovate spreading segments: the flowers light purple, appearing at the end of June, but seldom producing seeds in this climate. It is a native of North America.

The fifth resembles the sixth, but the stem is three times as high, and somewhat rugged: the leaves wider, and ovate-lanceolate: the corymb consisting of numerous flowers, with several peduncles from the uppermost axils of the leaves, erect, and fastigate into a sort of corymb of a dark purple colour. It grows naturally in Carolina, flowering from July to September.

The sixth species has the stalks near a foot and half high, dividing into three or four small branches towards the top, each terminated by a corymb of flowers: the lower leaves opposite, three inches long, and near half an inch broad at the base, ending in long acute points, smooth and sessile; the upper ones are alternate: the tube of the corolla twice the length of the calyx; segments of the border roundish, spreading, of a light purple colour: the flowers appear in June, but seldom produce seeds in this climate. It is a native of North America, flowering from June to August.

The seventh species has the stems almost upright, simple, and then divided into two branches: the leaves opposite on a simple stem, in five oppositions, softish, rugged; the upper ones alternate: the flowers from the partings of the stem and the axils of the alternate leaves, two together on separate pedicels: the calyx five-parted: the corollas pale blue, with a crooked tube: the flowers appear at the end of May, or beginning of June, but are rarely succeeded by seeds in this climate. It grows naturally in North America.

Culture.—These are generally increased by parting their roots, as they do not often produce seeds in this climate. The best time for performing this is in autumn, when the stalks begin to decay. The roots should not, however, be divided into too small heads, when they are expected to flower well the following summer; nor should they be parted oftener than every other year, as, when they are too often removed and parted, it greatly weakens the roots, so that they send out but few stalks, and those so weak as not to rise their usual height, and the bunches of flowers are much smaller.

The large root off-sets may be planted out at once where they are to remain; but the small ones in nursery-rows, for further increase in size.

When the roots are parted and removed, it is a good way to lay some old tan, or mulch, upon the surface of the ground about their roots, to prevent the frost from penetrating; for, as they will have put out new roots before winter, the frost, when it is severe, often kills the fibres, whereby the plants suffer greatly, and are sometimes wholly destroyed.

The first and sixth sorts may be increased pretty expeditiously by their spreading roots, but the others but slowly this way; of course it is a better method to have recourse to cuttings. The best season for planting the cuttings is about the end of April, or the beginning of the following month, when the young shoots from the roots, which are about two inches high, should

be cut off close to the ground, and their tops shortened, being then planted on a border of light loamy earth, and shaded from the sun until they have taken root; or if they are planted pretty close together, and covered with bell- or hand-glasses, or in pots, shading them every day from the sun, they will put out roots in five or six weeks; but on their beginning to shoot, the glasses should be gradually raised to admit the free air to them, otherwise they are apt to draw up weak, and soon spoil: as soon as they are well rooted, the glasses should be taken off, and the plants inured to the open air; being soon afterwards removed into a bed of good soil, planting them about six inches distance every way, shading them from the sun, and watering till they have taken new root; after which, when kept clean from weeds, they require no other care till autumn, when they should be removed into the borders or other parts, where they are designed to remain.

When some of the plants are put into pots, and sheltered under a hot-bed frame in winter, they flower stronger the following summer.

These plants succeed best in a moist rich mellow soil, growing taller, and flowering more strongly and in larger bunches. In poor dry soils they often die during the summer, when not constantly watered with care.

Some of the plants afford ornament in the borders, clumps, and other parts of pleasure-grounds; and those planted in pots to be placed in court-yards, or other places near the habitation, when they are in beauty, and being mixed with other flowers, are highly ornamental.

PHŒNIX, a genus containing a plant of the evergreen exotic tree kind.

It belongs to *Appendix Palmæ*, (*Diœcia Triandria*,) and ranks in the natural order of *Palmæ*, or *Palmæ*.

The characters are: that in the male flowers the calyx is an universal one-valved spathe: spadix branched: perianthium three-parted, very small, permanent: the corolla has three petals, concave, ovate, somewhat oblong: the stamina have three very short filaments: anthers linear, four-cornered, the length of the corolla: female flowers on a different plant, or on the same spadix: the calyx as in the male: the pistillum is a roundish germ: style awl-shaped, short: stigma acute: the pericarpium is an ovate, one-celled drupe: the seed single, bony, subovate, with a longitudinal groove.

The species is *P. dactylifera*, Date Palm-tree.

It rises to a great height in warm climates: the stalks are generally full of rugged knots, which are the vestiges of the decayed leaves, for

the trunks of these trees are not solid like other trees, but the centre is filled with pith, round which is a tough bark full of strong fibres while young, but as the trees grow old, this bark hardens and becomes woody: to it the leaves are closely joined, and in the centre rise erect, being closely folded or plaited together; but after they are advanced above the sheath which surrounds them, they expand very widely on every side the stem, and as the older leaves decay the stalk advances in height: the leaves when grown to a size for bearing fruit are six or eight feet long, and may be termed branches (for the trees have no other); these have narrow long leaves (or pinnae) set on alternately their whole length: the small leaves or lobes are towards the base three feet long, and little more than one inch broad; they are closely folded together when they first appear, and are wrapped round by brown fibres or threads, which fall off as the leaves advance, making way for them to expand; these never open flat, but are hollow like the keel of a boat, with a sharp ridge on their back; are very stiff, and, when young, of a bright green, ending with a sharp black spine. These trees have male flowers on different plants from those which produce the fruit, and there is a necessity for some of the male trees to grow near the females, to render them fruitful; or at least to impregnate the germ, without which the stones which are taken out of the fruit will not grow: the flowers of both sexes come out in very long bunches from the trunk between the leaves, and are covered with a spatha (or sheath) which opens and withers; those of the male have six short stamina, with narrow four-cornered anthers filled with farina. The female flowers have no stamina, but have a roundish germ, which afterwards becomes an oval berry, with a thick pulp inclosing a hard oblong stone, with a deep furrow running longitudinally: the bunches of fruit are sometimes very large. It is a native of the Levant.

Culture.—This plant may be increased by seed, procured from abroad, or taken out of the fruit, which should be sown as soon as possible in pots of light rich earth, plunging them in a tan hot-bed, or in the bark-bed in the stove, giving moderate waterings; when they soon come up; and when a few inches high, they should be pricked out into separate small pots, plunging them in the hot-bed or bark-bed; where they must remain, giving frequent waterings, and shifting them into larger pots, according as their progress of growth may require. When they are removed, great care should be taken not to injure their large roots, or to overpot them.

This, like the rest of the Palm tribe, has no other branches than its large leaves, each of which is composed of a leaf and branch, always arising from the top; and as the old leaves fall, the stem forms itself and advances in height; but although the leaves grow very tall in a few years, the stem advances but slowly, and can never be expected to arrive at a flowering and fruiting state in this climate: it, however, merits a place in the hot-house collections for its singularity.

The berries of this tree are the dates of the shops, which are imported from Africa and the countries in the Levant.

PHYLICA, a genus containing plants of the shrubby, evergreen, exotic kind. Bastard Alaternus.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Dumosæ*.

The characters are: that the calyx is a common receptacle of the fructifications collecting the flowers into a disk: perianthium proper one-leaved, five-cleft, turbinate, mouth villose, permanent: there is no corolla: scalelets five, acuminate, one at the base of each division of the calyx, converging: the stamina have five filaments, very small, inserted under the scalelet: anthers simple: the pistillum is a germ at the bottom of the corolla: style simple: stigma obtuse: the pericarpium is a roundish capsule, three-grained, three-celled, three-valved, crowned: the seeds solitary, roundish, gibbous on one side, angular on the other.

The species are: 1. *P. ericoides*, Heath-leaved Phylica; 2. *P. plumosa*, Woolly-leaved Phylica; 3. *P. luxifolia*, Box-leaved Phylica.

The first is a low bushy plant, seldom rising more than three feet high: the stalks are shrubby and irregular, dividing into many spreading branches, subdividing into smaller ones: the young branches are closely beset with short, narrow, acute-pointed, sessile leaves, of a dark green, and continuing all the year. At the end of every shoot, the flowers are produced in small clusters sitting close to the leaves; they are of a pure white, begin to appear in the autumn, continue in beauty all winter, and decay in spring. It grows naturally at the Cape, and the flowers are slightly odoriferous.

The second species has an erect shrubby stalk, which rises near three feet high, covered with a purplish bark, and here and there some white down upon it: the leaves are narrow, short, acute-pointed, sessile, alternate on every side, thick, nerved, dark green on their upper surface, but hoary on their under: flowers collected in small heads at the end of the branches, white,

woolly, fringed on their borders, cut into six acute segments at top. It flowers from March to May.

The third rises with a shrubby upright stalk five or six feet high, when old covered with a rough purplish bark, but the younger branches have a woolly down: the leaves are thick, the size of those of the box-tree, veined, smooth and of a lucid green on their upper side, but hoary on their under; they have short footstalks, and stand without order on the branches: the flowers are collected in small heads at the ends of the branches; they are of an herbaceous colour, and make no great appearance. It flowers during a great part of the year.

Culture.—They are chiefly increased by cuttings and slips of the young shoots.

In spring, as about March or April, a quantity of young cuttings, or slips of the small shoots, should be taken off, planting them in pots of rich earth, plunging them in a hot-bed, or in the bark-bed in the stove; giving frequent waterings, and occasional shade from the sun, when they will soon emit roots, and become proper plants fit for potting off separately in autumn: or the young cuttings or slips may be planted any time in summer, particularly in June and July, in pots as above, and placed under a hot-bed frame, or covered close with hand glasses, being watered and shaded; when they will also grow, but not be so forward as those of the spring planting.

They are somewhat tender plants, requiring shelter in winter in this climate: of course they must always be kept in pots, and placed among the green-house exotics, where they will effect a very agreeable variety at all seasons, and flower annually a great part of the autumn and winter, but do not produce seed in this climate.

PHYLLANTHUS, a genus furnishing plants of the evergreen exotic tree and shrubby kind. Sea-side Laurel.

It belongs to the class and order *Monoecia Triandria*, and ranks in the natural order of *Tricoccæ*.

The characters are: that the male calyx is a one-leaved perianthium, six-parted, bell-shaped, coloured: segments ovate, spreading, blunt, permanent: there is no corolla, except the calyx be called so: the stamina have three filaments, shorter than the calyx, approximating at the base, distant at the tips: anthers twin: females—the calyx a perianthium as in the males: there is no corolla: nectary a rim of twelve angles, surrounding the germ: the pistillum is a roundish germ, obtusely three-cornered: styles three, spreading, bifid: stigmas blunt: the pericarpium is a roundish capsule, three-grooved, three-celled;

cells bivalve : the seeds are solitary and roundish.

The species are : 1. *P. Niruri*, Annual Phyllanthus ; 2. *P. grandifolia* Great-leaved Phyllanthus ; 3. *P. Emblica*, Shrubby Phyllanthus.

The first has a filiform, long, white root : the stem herbaceous, about a foot high, branched, erect, roundish, even : the leaves alternate, distant, often only terminating : the petioles filiform, bearing both leaves and flowers : the leaflets contract every evening, turning their under side outwards : the flowers are produced on the under side of the leaves along the midrib, and turn downwards. It usually flowers here from June to October. It is common in Barbadoes.

The second species rises with a tree-like stem and branches : the leaves are large, ovate, obtuse, and entire. It is a native of North America.

The third rises in its native situation, with a tree-like stem, to the height of twelve or fourteen feet, but in this climate not more than half that height, sending out from the side many patulous branches : the leaves have very narrow leaflets. It has a berry-like fruit, and is a native of the Indies.

Culture.—These plants, where seeds can be procured from their native situations, may be raised in that way. They should be sown in pots filled with light earth, and plunged in a hot-bed ; and when the plants have acquired some growth, they should be planted out into separate pots filled with the same sort of mould ; being replunged in the hot-bed, due shade and water being given, until they become perfectly rooted ; after which they should be constantly kept in the bark-bed of the stove, and have the management of other plants of the same tender sort.

They may also sometimes be raised by planting out slips, or by layers managed in the same way as those from seeds.

They afford a fine variety in their beautiful foliage, and the flowery kinds have a singular effect in their flowers.

PHYLLIS, a genus containing plants of the shrubby evergreen exotic kind.

It belongs to the class and order *Pentandria Digynia*, and ranks in the natural order of *Stelatae*.

The characters are : that the calyx has no umbel (but a panicle) : perianthium very small, superior, two-leaved, obsolete : the corolla has five petals, lanceolate, obtuse, revolute, scarcely connected at the base : the stamina have five filaments, shorter than the corolla, capillary, flaccid : anthers simple, oblong : the pistillum

is an inferior germ : style none : stigmas two, awl-shaped, pubescent, reflex : there is no pericarpium : fruit turbinate-oblong, blunt, angular : the seeds two, parallel, convex and angular on one side, flat on the other, wider at top.

The species is *P. Nulla*, Bastard Hare's-Ear.

It rises with a soft shrubby stalk about two or three feet high, which is seldom thicker than a man's finger, of an herbaceous colour, and full of joints. These send out several small side branches towards the top, garnished with spear-shaped leaves near four inches long, and almost two broad in the middle, drawing to a point at each end ; they are of a lucid green on their upper side, but pale on their under, having a strong whitish midrib, with several deep veins running from it to the sides : the leaves are for the most part placed by threes round the branches, to which they sit close : the flowers are produced at the ends of the branches, in loose panicles ; are small, of an herbaceous colour at their first appearance, but before they fade, change to a brown or worn out purple, and are cut into five parts to their base, where they are connected, and fall off without separating. It is a native of the Canary Islands, flowering in June and July.

Culture.—The plants may be increased by sowing the seeds in the early spring months, as about March, in pots filled with light earth, and plunged in a hot-bed ; and when the plants have attained some growth, they should be planted out in separate pots, replunging them in the hot-bed, due shade being given till they become well rooted. In the summer season they should be set out in a sheltered situation, so as to have the morning sun, and be frequently watered. In the winter they must be well sheltered from frost, but have as much air as possible in mild weather.

In the second year, when the plants are shaken out of the pots and placed in a proper situation in the open ground, they flower better and afford more perfect seeds than when kept in pots.

They may also be raised by cuttings planted out in the summer season.

New plants should be raised every two or three years, as they do not last long.

They afford an agreeable variety among other evergreen plants of the green-house kind.

PHYSALIS, a genus comprising plants of the herbaceous and shrubby ornamental kind.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Luridae*.

The characters are : that the calyx is a one-leaved perianthium, ventricose, half-five-lobed,

small, five-cornered, with acuminate segments, permanent: the corolla one-petalled, wheel-shaped: tube very short: border half-five-cleft, large, plaited: segments wide, acute: the stamina have five filaments, awl-shaped, very small, converging: anthers erect, converging: the pistillum is a roundish germ: style filiform, generally longer than the stamens: stigma blunt: the pericarpium is a subglobular berry, two-celled, small, within a very large, inflated, closed, five-cornered, coloured calyx: the receptacle kidney-form, doubled: the seeds very many, kidney-form, compressed.

The species are: 1. *P. angulata*, Tooth-leaved Winter Cherry; 2. *P. pubescens*, Woolly Winter Cherry; 3. *P. Alkekengi*, Common Winter Cherry; 4. *P. Pennsylvanica*, Pennsylvanian Winter Cherry; 5. *P. viscosa*, Clammy Winter Cherry; 6. *P. somnifera*, Clustered Winter Cherry; 7. *P. flexuosa*, Flexuous Italian Winter Cherry; 8. *P. arborescens*, Tree-like Physalis, or Winter Cherry; 9. *P. Curassavica*, Curassavian Winter Cherry.

The first has a straight stem, the thickness of the little finger, about a foot high, three-cornered below, four-cornered above, as are also the branches, which come out obliquely from top to bottom, in alternate order, and are thicker at the base: the lower leaves wider and rounder than those about the middle of the stem, and these larger than those of the branches, deeply toothed or jagged: the flowers five-cornered, of an extremely pale yellow colour, with spots of a darker yellow at the base. It is a native of both the Indies, &c.

There is a variety which is taller, with entire leaves, smaller flowers of a paler yellow colour.

The second species branches out very wide close to the ground, and the branches frequently lie upon it; they are angular and full of joints, dividing again into smaller branches: the leaves are on pretty long footstalks, about three inches long and almost two broad, having several acute indentures on their edges: the flowers produced on the side of the branches upon short, slender, nodding peduncles; they are of an herbaceous yellow colour with dark bottoms, and are succeeded by large, swelling bladders; of a light green, inclosing berries as large as common cherries, which are yellowish when ripe. It flowers in July, and is a native of Virginia.

These are both annual plants.

The third has perennial roots, creeping to a great distance: they shoot up many stalks in the spring a foot high or more: the leaves of various shapes, some angular and obtuse, others oblong and acute-pointed, of a dark green, on long footstalks: the flowers axillary, on slender

peduncles, white, appearing in July; the berry round, the size of a small cherry, inclosed in the inflated calyx, which turns of a deep red in the autumn. It is a native of the South of Europe, &c.

The fourth species has many procumbent or erect stems, scarcely a foot in height, somewhat flexuose, roundish or obscurely angular on the top, at the flowers branched, having an obscure down scattered over them: the leaves are alternate, ovate, blunt, serrate-repand, almost naked above, obscurely tomentose underneath, next the flowers in pairs: the flowers axillary on very short peduncles, larger than those of the common sort, and of a pale yellow colour. They are succeeded by very small yellowish berries, which ripen in the autumn when the season proves warm. It is a native of North America, and flowers from July to September.

The fifth has a creeping root, sending up a great number of smooth stalks, about a foot high, dividing towards the top into small spreading branches: the leaves heart-shaped or ovate, about three inches long, and two broad near their base, entire, rough to the touch, of a pale yellowish green, alternate, on pretty long footstalks: the flowers are towards the top, axillary, on long slender peduncles, of a dirty yellow colour with purple bottoms. They appear in June and July, and are succeeded by viscous berries about the size of the common sort, of an herbaceous yellow colour, inclosed in a light-green swelling bladder. It is a native of America.

The sixth species rises with a shrubby stalk, near three feet high, dividing into several branches which grow erect, and are covered with a woolly down: the leaves ovate-lanceolate, almost three inches long, and an inch and a half broad in the middle, downy, and on short petioles: the flowers small, of an herbaceous white colour, sitting very close to the branches, and succeeded by small berries nearly of the same size as the common winter cherry, and red when ripe. It is a native of Spain, Sicily, &c., flowering in July and August.

The seventh rises to the height of five or six feet, sending out long flexuose branches covered with a gray bark: the leaves oblong-ovate, often placed opposite, sometimes by threes round the branches, to which they sit close: the flowers in clusters at the base of the petioles, small, of an herbaceous yellow colour: they are succeeded by round purplish berries having ten cells, each including one seed. It flowers in July and August, but not unless the season is warm. It is a native of the East Indies.

The eighth species has a shrubby stalk,

ten or twelve feet high, dividing towards the top into several small branches, covered with a gray hairy bark: leaves on the lower part alternate, but towards the end of the branches opposite; the lower leaves from three to four inches long, and two broad in the middle, drawing to a point at both ends; they are of a pale green, and downy: the flowers from the axils towards the end of the branches, one or two at the same joint opposite, on short nodding peduncles; are small, of a pale dirty yellow colour, with purple bottoms: berries small, spherical, red, inclosed in an oval dark-purple bladder. It flowers in June and July.

The ninth has a perennial creeping root: the stalks several, slender, about a foot high, becoming somewhat woody, but seldom lasting above two years; the leaves alternate, on short footstalks; they are about two inches long, and an inch and half broad: the flowers axillary towards the top, on short slender peduncles: petals small, sulphur-coloured with dark-purple bottoms: they appear in July and August, but are rarely succeeded by berries in this climate. It is a native of Curassao in the West Indies.

Culture.—These plants are all capable of being increased by seeds; the second, third, fourth, and fifth sorts, also by parting the roots; the sixth, seventh, eighth, and ninth, likewise by cuttings.

In the first sort, the seed should be sown in the early spring, as April, in pots of light earth, plunging them in a moderate hot-bed. When the plants have acquired a few inches in growth they should be removed into separate pots, gradually inuring them to the open air, in order that they may be removed with balls into the clumps or borders. But it is probably a better method to sow them in the latter end of May in the places where they are to remain, as they do not bear transplanting well.

They must be raised annually.

In the herbaceous kinds the seeds should be sown in the autumn as soon as they are ripe, or early in the spring, in the beds, borders, or clumps where they are to remain; or they may be transplanted into other beds to remain till the following autumn, when they may be removed to the situations where they are to remain.

The roots may be parted either in the early autumn or spring season, when the weather is mild. The divided parts should have root-fibres left at the bottoms and a bud in each at the tops in order to their succeeding properly.

In the sixth and seventh sorts, the seed should be sown in pots of light mould in the early spring and plunged in a mild hot-bed.

When the plants have had a little growth they should be pricked out into separate small pots, proper shade and water being given; being afterwards managed as the shrubby exotics of less-tender plants.

They may likewise be raised from cuttings, made in the later spring or summer months, which should be placed in pots of light mould and plunged in the hot-bed, due shade and water being given till they have stricken root.

And the two last sorts may be raised from seeds or cuttings in the same way, by the aid of the bark hot-bed of the stove.

The first and the other herbaceous sorts are curious ornamental plants in the borders, clumps, and other parts of pleasure-grounds, and the four best shrubby sorts in the green-house and stove collections.

PHYTOLACCA, a genus affording plants of the herbaceous hardy kinds.

It belongs to the class and order *Decandria Decagynia*, and ranks in the natural order of *Miscellaneæ*.

The characters are: that there is no calyx, unless the corolla be called a coloured calyx: the corolla five petals, roundish, concave, spreading, bent in at top, permanent: the stamina have eight, ten, or twenty, awl-shaped filaments, the length of the corolla: anthers roundish, lateral: the pistillum is an orbiculate germ, depressed, divided externally by swellings, ending in eight or ten very short spreading-reflex styles: the pericarpium is an orbiculate berry, depressed, marked with ten longitudinal grooves, umbilicated with the pistils, and having as many cells: the seeds are solitary, kidney-form and smooth.

The species cultivated are: 1. *P. octandra*, White-flowered Phytolacca; 2. *P. decandra*, Branching Phytolacca, or Virginian Poke; 3. *P. icosandra*, Red Phytolacca; 4. *P. dioica*, Tree Phytolacca.

The first has the stalk herbaceous, two feet high, about the size of a man's finger, and divides at top into two or three short branches: the leaves ovate-lanceolate, near six inches long, and almost three broad; they have a strong midrib, and several transverse veins, are of a deep green, and the footstalks are an inch and half long: the peduncles come out from the side of the branches opposite to the leaves, are seven or eight inches long; the lower part, about two inches in length, is naked; the remainder has sessile flowers, white with a blush of purple in the middle, cut into five segments almost to the bottom, and having from eight to fourteen stamens, and ten styles: the berries flat, with ten deep furrows.

In some places it is found a palatable wholesome green: the tender stalks are frequently served up for young asparagus.

In the second species the root is very thick and fleshy, as large as a man's leg, divided into several thick fleshy branches, which run deep in the ground: the stems three or four, herbaceous, as large as a good walking-stick, of a purple colour, six or seven feet high, dividing into many branches at the top: the leaves five inches long, and two inches and a half broad, rounded at their base, but terminating in a point, placed without order on short footstalks; they are of a deep green, and in the autumn change to a purplish colour: the peduncles come out from the joints and divisions of the branches, and are about five inches long; the lower part is naked, but the upper half sustains a number of flowers ranged on each side like common currants. Each flower stands upon a pedicel half an inch long, and the petals are purplish: the berry depressed, with ten furrows. It flowers in July and August. It is a native of Switzerland, &c.

In some places the young shoots are boiled and eaten as spinach.

The third rises with an herbaceous stalk, from two to three feet high, with several longitudinal furrows, and changes at the end of summer to purple. It divides at top into three or four branches: the leaves are lanceolate, six or seven inches long, and almost three broad in the middle, of a deep green, on short footstalks; some are alternate, others opposite, and they are frequently oblique to the footstalk: the peduncles come out from the side of the branches opposite to the leaves; they are nine or ten inches long, the lower part being naked, but for a shorter space than in the other sorts; the upper part narrow and commonly inclined: the flowers are larger, white within, of an herbaceous colour on their edges, and purplish on the outside, on short pedicels.

The fruit is a globular berry. It is annual.

The fourth is a shrub two fathoms in height: the stem upright, a little branched, very thick, gray: the leaves scattered, oblong-ovate, acuminate, entire, smooth, flat or ascending on the sides, five inches long, and two inches and a half wide: the petioles spreading, cylindrical, reddish, equal to half the leaf in length: the racemes terminating, peduncled, solitary, pendulous, bracteate, six inches long: the flowers scattered, pedicelled, spreading very much, whitish green: the males five or six lines in breadth, the females smaller by half. Both the male and the female plants flower every spring,

but the latter is probably barren. It is a native of South America.

Culture.—The three first sorts may be increased by seeds, which should be sown in pots, in the spring, and plunged in a moderate hot-bed: when the plants have had a few inches growth, they should be removed into separate pots in the first and third sorts, but in the second into the borders or other parts, allowing them good room. The two former may be set out in warm borders or other places during the summer in the pots, being carefully watered, shaded, and kept free from weeds.

The fourth sort may be raised by planting cuttings in the summer season, in pots filled with light earth, plunging them in the bark hot-bed and covering the pots with hand glasses, proper shade being given. When well rooted, they should be removed into separate pots of a small size, re-plunging them in the hot-bed with proper shade till rooted, when they should be gradually inured to the open air, being removed into a moderate stove during the winter season.

They afford ornament and variety among potted plants of the stove kind; and the second sort, in the borders of the natural ground.

PIGEON PEA. See *CYTISUS*.

PIG-NUT. See *BUNIUM*.

PILEWORT. See *RANUNCULUS*.

PIMENTO. See *MYRTUS*.

PIMPERNEL. See *ANAGALLIS*.

PIMPINELLA, a genus containing a plant of the annual kind.

It belongs to the class and order *Pentandria Digynia*, and ranks in the natural order of *Umbellatæ* or *Umbellifera*.

The characters are: that the calyx is an universal umbel of many rays: partial of still more: involucre universal none: partial none: perianthium proper scarcely observable: the corolla universal almost uniform: florets all fertile: proper, petals five, inflex-cordate, almost equal: the stamina have five filaments, simple, longer than the corolet: anthers roundish: the pistillum is an inferior germ: styles two, very short: stigmas subglobular: there is no pericarpium: fruit ovate-oblong, bipartite: the seeds two, oblong, narrower towards the top, on one side convex and striated, on the other flat.

The species cultivated is *P. Anisum*, Anise.

It has an annual root: the lower leaves are divided into three lobes, which are deeply cut on their edges: the stem a foot and half high, dividing into several slender branches, which have narrow leaves on them, cut into three or four narrow segments: the umbels pretty large and

loose, on long peduncles: the flowers small, yellowish white: the seeds oblong, swelling. It flowers in July; and if the season prove warm the seeds will ripen in autumn. It is a native of Egypt.

The seeds have an aromatic smell, and a pleasant warm taste, accompanied with a considerable degree of sweetness.

Culture.—The seeds should be sown in the early part of April on a dry warm border, where the plants are to remain, being afterwards properly thinned out and kept free from weeds. These plants, however, seldom afford much profit by their seeds in this climate.

They produce variety in the borders, &c., of pleasure-grounds, as well as in pots in other places when cultivated in that way.

PINASTER. See PINUS.

PINEA. See PINUS.

PINE-APPLE. See BROMELIA.

PINE, SCREW. See PANDANUS.

PINE-TREE. See PINUS.

PINGVIN. See BROMELIA.

PINUS, a genus containing plants of the evergreen and deciduous tree-kinds.

It belongs to the class and order *Monoecia Monadelphica*, and ranks in the natural order of *Coniferae*.

The characters are: that the male flowers are disposed in racemes: the calyx has scales of the bud opening, and no other: there is no corolla: the stamina have very many filaments, connected at bottom into an upright column, divided at top: anthers erect, naked: female flowers on the same plant: calyx is a subovate strobile, consisting of scales which are two-flowered, oblong, imbricate, permanent, rigid: there is no corolla: the pistillum is a very small germ: style awl-shaped: stigma simple: there is no pericarpium: strobile serves for a calyx, having before been closed, but now only converging: the seed is a nut augmented by a membranaceous wing which is larger than the seed, but less than the scale of the strobile, oblong, straight on one side, gibbous on the other.

The species are: 1. *P. sylvestris*, Wild Pine-Tree; 2. *P. Pinaster*, Pinaster, or Cluster Pine-Tree; 3. *P. inops*, Jersey Pine-Tree; 4. *P. resinosa*, American Pitch Pine-Tree; 5. *P. halepensis*, Aleppo Pine-Tree; 6. *P. Pinea*, Stone Pine-Tree; 7. *P. Taeda*, Torch Pine, or Three-leaved Virginia Pine; 8. *P. palustris*, Swamp Pine-Tree; 9. *P. cembra*, Siberian Stone Pine-Tree; 10. *P. occidentalis*, West Indian Pine-Tree; 11. *P. Strobus*, Weymouth Pine-Tree; 12. *P. Cedrus*, Cedar of Lebanon; 13. *P. pendula*, Black Larch-Tree; 14. *P. Larix*, Com-

mon White Larch-Tree; 15. *P. Picea*, Silver Fir-Tree; 16. *P. Balsamea*, Balm of Gilead Fir-Tree; 17. *P. canadensis*, Hemlock Spruce Fir-Tree; 18. *P. nigra*, Black Spruce Fir-Tree; 19. *P. Abies*, Norway Spruce Fir-Tree; 20. *P. alba*, White Spruce Fir-Tree; 21. *P. orientalis*, Oriental Fir-Tree.

The first in a favourable soil grows to the height of eighty feet, with a straight trunk: the bark is of a brownish colour and full of crevices: the leaves issue from a white truncated little sheath in pairs; they are linear, acuminate, quite entire, striated, convex on one side, flat on the other, mucronate, bright green, smooth, from an inch and half to two inches or a little more in length, shorter than in the Pinaster and Stone-Pine, broader, twisted, and of a grayish colour: the scales of the male catkins roll back at top, and are feathered; the inner and upper scales of the cones gradually terminate in a short awn, but the lower scales have none; the scales open very readily; the cones small, pyramidal, ending in narrow points, of a light colour, with small seeds. It is here often called Scotch Fir, from its growing naturally in the mountains of Scotland; but is common in most parts of Europe, particularly in the northern parts. The wood affords the red or yellow deal, which is the most durable of any of the kinds yet known: the leaves are much shorter than those of the Pinaster and Stone Pine, broader, of a grayish colour and twisted: the cones are small, pyramidal, and end in narrow points; they are of a light colour, and the seeds are small.

The trunk affords masts to our navy, and from it and the branches tar and pitch are obtained, as also by incision barras, Burgundy pitch and turpentine.

There are several varieties: as the Tartarian, which has a great resemblance to it, but the leaves are broader, shorter, and their points are more obtuse; they emit a strong balsamic odour when bruised: the cones are very small, as are also the seeds, some of which are black, and others white. It grows naturally in Tartary.

The Mountain, or Mughoe, which has very narrow green leaves, grows sometimes by pairs, sometimes by threes from the same sheath, generally standing erect: the cones are of a middling size and pyramidal: the scales flat, having each a small obtuse rising, but very compact till they are opened by the warmth of the sun the second spring: the seeds of this are much less than those of the second sort, but larger than those of the first. It is a native of the Swiss mountains, where it is often called Torch Pine, growing to a great height.

The Sea Pine, which has smooth leaves: the cones are very long and slender; and the seeds are about the same size with those of the second species. It grows in the maritime parts of Italy, &c.

Others are likewise mentioned by writers.

The second species grows to a large size: the branches extend on every side to a considerable distance, and whilst the trees are young, they are fully furnished with leaves, especially when they are not so close as to exclude the air from those within; but as they advance in age the branches appear naked, and all those which are situated below become unsightly; for this reason, and because the timber is much preferable to it, the first species has been more generally cultivated. Its branches grow at a wider distance than those of the first sort, and are more horizontal: the leaves much larger, thicker, and longer, grow straight, have a broad surface on their inside, which has a furrow or channel running longitudinally; they are of a darker green and their points obtuse: the cones are seven or eight inches long, pyramidal, with pointed scales: the seeds oblong, a little flattened on their sides, and have narrower wings on their tops. It grows naturally in the mountains of Italy, &c.

The third never rises to any great height, and is the least esteemed in the country of all the sorts. While the trees are young they make a pretty good appearance, but when they get to the height of seven or eight feet they become ragged and unsightly, and are seldom worth cultivating in this climate. It is a native of North America.

The fourth species is also a native of North America, and may be cultivated in this climate.

The fifth species branches out on every side near the root; they at first grow horizontally, but turn their ends upwards; their bark is smooth and of a dark gray colour: the leaves are long and very narrow, of a dark green, and if they are bruised emit a strong resinous odour: the cones come out from the side of the branches; are not much more than half the length of those of the second species, but are full as large at their base: the scales are flattened, and the point of the cones obtuse: the seeds much less, but of the same shape. It is a native of Aleppo, &c.

The sixth has the leaves not quite so long as those of the second species, and of a grayish or sea-green colour: the cones are not more than five inches long, but very thick, roundish, and end obtusely: the scales are flat, and the seeds more than twice the size of those of the second

sort: the kernels are frequently served up in deserts during the winter season in Italy and the South of France.

It grows to a considerable height, with a straight and fair stem, but rough bark: the leaves contribute to diversify the scene in plantations, as they differ in colour from the other sorts, and are arranged in a different manner: the cones are very large and turbinate, striking the eye by their bold appearance when hanging on the trees; and when closely examined, afford ornament from the beautiful arrangement of their scales. It is a native of the South of France, &c., is chiefly grown for ornament and the kernels which it affords.

The seventh has very long narrow leaves, growing by threes out of each sheath: the cones are as large as those of the sixth sort, but more pointed, and the scales looser, opening horizontally and discharging the seeds. The wood of this tree is like that of the first sort, but has more resin. It is a native of North America, and is cultivated under the name of Frankincense Pine.

There are different varieties; as the Three-leaved Virginia, which has the leaves long, generally three in each sheath: the cones in clusters round the branches, as long as those of the second sort, but with rigid scales: the seeds also nearly as large as those of it. It grows naturally in Virginia, and other parts of North America, where it rises to a great height.

The others differ but little from this.

The eighth species, in its native swampy situation, grows to the height of twenty-five or thirty feet: the leaves are a foot or more in length, growing in tufts at the ends of the branches, having a singular appearance. The wood is of little use but for fuel. It is a native of Carolina and Georgia.

The ninth is often confounded with the sixth sort; but the cones of the latter are short and roundish, with close scales, whereas those of it are long and the scales looser: the leaves have a near resemblance; but the plants raised from seeds of that sort make much greater progress than this, which can scarcely be kept alive in this climate. It is a native of Switzerland, Siberia, &c.

The tenth species has been confounded with the eleventh sort, and is a native of Hispaniola.

The eleventh is one of the tallest species, often attaining a hundred feet in height in its native country: the bark is very smooth and delicate, especially whilst the tree is young: the leaves are long and slender; they are pretty closely placed on the branches, and make a fine

appearance: the cones are long, slender, and very loose, opening with the first warmth of the spring; so that if the seeds are not gathered in winter, the scales open and let them out: the wood is esteemed for masts of ships. It is often called the White and New England Pine, and is highly ornamental.

The twelfth species is a noble tree, which has a general striking character of growth so peculiar to itself that no other tree can possibly be mistaken for it. It is placed with the Larch, in the genus with Firs and Pines, as agreeing with the former in its foliage, with the latter in being evergreen. Its arms grow in time so weighty as often to bend the very stem and main shaft: the leaves much resemble those of the Larch, but are somewhat longer and closer set, erect, and perpetually green, which in that are not; but hanging down, dropping off, and deserting the tree in winter: the cones are tacked and ranged between the branch-leaves, in such order as nothing appears more curious and artificial, and at a little distance exceedingly beautiful: they have the bases rounder, shorter, or rather thicker, and with blunter points; the whole circumzoned, as it were, with pretty broad thick scales, which adhere together in exact series to the very summit, where they are somewhat smaller, but the entire lorication smoother couched than those of the Firs; within these repositories, under the scales, nestle the small nutting seeds, of a pear-shape: the cones grow upon the upper part of the branches, and stand erect, having a strong, woody, central style, by which they are firmly attached to the branch, so as with difficulty to be taken off; and which remains upon the branch after the cone is fallen to pieces, which never drops off whole, as in the Pine sort. It is a native of Mount Lebanon, &c., and is very lasting, being indestructible by insects.

The Cedar is now so far naturalized to our country as to produce ripe seeds; we may therefore have supplies without depending on the cones from the Levant: but it is found that they are more apt to produce and ripen their cones in hard winters than in mild ones; which is a plain indication that they will succeed even in the coldest seasons of the northern parts of the Island, where, as well as in the other parts, they might be propagated to great advantage.

The thirteenth sort is not much cultivated; but a particular sort of it has been brought from North America, which differs from the European sort in having darker shoots, but which has not long been known in Europe, though it grows plentifully in some of the north-

ern parts of America. As it does not promise to make so large trees as the European sort, it should be planted with those of lower growth, to make a variety. It endures the severest cold of this climate.

The fourteenth is of quick growth, rising to the height of fifty feet: the branches are slender, and their ends generally hang down: the leaves are long and narrow, in clusters from one point, spreading open above like the hairs of a painter's brush, of a light green, and falling off in autumn; in which circumstance this and the preceding differ from all the other species. In the month of April the male flowers appear, disposed in form of small cones: the female flowers are collected into egg-shaped obtuse cones, which in some have bright purple tops, but in others they are white; this difference is accidental, for seeds taken from either will produce plants of both sorts: the cones are about an inch long, and the scales are smooth; under each scale two winged seeds are generally lodged. It is a native of the South of Europe, and highly useful for planting in bleak situations, for the purpose of timber, &c.

There are different varieties:—the American, the Siberian, and the Chinese, require a colder climate than England, for the trees are apt to die in summer here, especially if they are planted on a dry soil: the cones of these which have been brought to England seem to be in general larger than those of the common sort; but there is so little difference between the trees in their characteristic notes, that they cannot be distinguished as different species, though in the growth of the trees there is a remarkable difference.

In the last, the cones are much larger than those of the common sort, and end in acute points: the scales prominent like those of the first species, and have little resemblance to those of the Larch. They are of a shrubby, spreading, but so hardy, as to thrive in the open air without any protection.

In the first, of which the branches are more slender, with a bark more inclining to yellow, and the scars more slender and clustered, the leaves are more tender, narrow, more glaucous, and the outer ones in each bundle shorter: cones only one-third of the size, blunt, with scales scarcely exceeding twelve in number, thinner, more shining, retuse-emarginate; the wings of the seeds are straight, more oblong, narrower, and, together with the seed itself, of a more diluted gray colour.

In the second, the bark of the branches is of an ash-coloured gray: the leaves a little wider, bright green, all nearly equal, commonly more

than forty in a bundle: the cones an inch long, with above thirty woody, striated, rounded, entire scales: the seeds brownish-gray, with sub-triangular wings somewhat bent in. In both, the cones are bent upwards on very short peduncles.

It is observed by the editor of Miller's Dictionary, that "no tree is more valuable, or better deserves our attention in planting than the Larch." It is a native of the South of Europe and Siberia.

The timber is not only used in houses, but in naval architecture also. "It seems to excel," he says, "for beams, doors, windows, and masts of ships: it resists the worm: being driven into the ground it is almost petrified, and will support an incredible weight: it bears polishing excellently well, and the turners abroad much desire it. It makes everlasting spouts, pent-houses and featheredge, which needs neither pitch or painting to preserve them; excellent pales, posts, rails, props for vines, &c.; to these we may add the pallettes on which painters separate and blend their colours.

The fifteenth species is a noble upright tree: the branches not very numerous, but the bark smooth and delicate: the upper surface of the leaves of a fine strong green, and their under has two white lines running lengthwise on each side of the midrib, giving the leaves a silvery look, from which it takes its name: the cones are large and grow erect, and when warm weather comes on soon shed their seeds: the scales wide, deltoid, rounded above, below beaked, and appendicled with a membranaceous spatulate dorsal ligule, terminated by a recurved dagger-point: the nuts rather large, membranaceous, variously angular, dun-coloured. It is a native of Switzerland, &c.

It has been observed in Ireland, that no tree grows so speedily to so large a size as the Silver Fir.—Some at forty years growth, in a wet clay on a rock, measuring twelve feet in circumference at the ground, and seven feet and a half at five feet high; one tree containing seventy-six feet of solid timber. The earl of Fife also remarks, that no trees make a greater progress than this and the Larch. It is found to be excellent for boat-building.

The sixteenth is a beautiful tree, which rises with an upright stem: the leaves are dark-green on their upper surface, and marked with whitish lines underneath: the cones are roundish and small: the buds and leaves are remarkably fragrant. From wounds made in this tree a very fine turpentine is obtained, which is sometimes sold for the true Balm of Gilead. It grows to

a large size in America, but has not done so in this climate.

It has very much the habit of the Silver Fir, but the leaves are wider and blunter, disposed on each side along the branches like the teeth of a comb, but in a double row, the upper one shorter than the under: underneath marked with a double glaucous line, and each has eight rows of white dots, and are often cloven at top. It is a native of Virginia.

The seventeenth species is a beautiful but delicate tree, and must have a good soil, with a warm situation; and it will be improved by tying its leading shoot to a stake annually as it advances.

It has the cone of the size and shape of a small hen's egg, and the whole of an ash-coloured bay: the scales coriaceous, thick, triangular, the outer side rounded and somewhat crenulate: the nuts a little smaller than in the Black Spruce, with a winged membrane on the outer side only. It is a native of many parts of North America, and does not thrive well in this climate.

The eighteenth, or Black Spruce, has shorter leaves, whiter on their under side than the White: the cones also are smaller and more compact. There is also a Red Spruce; but there seems to be no difference between this and the Black, either in the cones which have been brought from Newfoundland, or the young plants which have been raised in gardens in this climate.

The appellations of White and Black are given from the colour of the bark, as their is little difference in the colour of the wood, and the leaves of the Black are whiter on their under side than those of the White. They are both natives of North America;—the White upon the mountains; the Black upon the low grounds, generally in bogs or swamps. The first is by much the largest tree. This sort is easily known by its narrow leaves, placed on every side of the branches, and its long pendulous cones, which do not fall to pieces on the tree, but drop off entire the following summer: the scales open and emit the seeds on the first warmth of the spring.

There is a variety of this tree cultivated under the title of the Long-coned Cornish Fir, in which the leaves are longer, broader, of a lighter colour, and fuller on the branches: the cones also longer.

The nineteenth species is the loftiest of European trees, attaining a height from 125 to 150 feet, with a very straight trunk, and throwing out its spreading branches so as to form an

elegant pyramid: the leaves are clustered, without order, from an oblong cortical scale, four-cornered, drawn out into a sharp point, thickish, commonly curved a little; compressed, slightly keeled on both sides, shining on the upper surface: the male cones or catkins are ovate, scattered in the axils of the leaves, purple: the young female cones are also purple; and when ripe pendulous: they have eight rows of scales in a spiral, each row having from twenty to twenty-three scales, in each of which are two seeds. It is a native of Norway.

There are two principal varieties: the White and the Red, both of which afford the white deals. And *Burgundy Pitch* is prepared from the resin procured from this tree by boiling and straining it through a cloth.

There is no tree that yields greater profit than the Spruce Fir in cold land; no tree is more beautiful standing single on turf in large plantations, or more useful for shelter in cold soils and situations.

The twentieth is distinguished from the Black Spruce by the marks which have been given under the eighteenth species.

The twenty-first species was found in the Levant, and may be cultivated for variety.

Culture.—In all the sorts and varieties the increase is effected by means of seeds, which may be obtained from the well ripened cones by exposing them to the heat of a gentle fire or that of the sun, in which way the cells open and the seeds may be readily taken out. When the cones are not made use of in this way, they will remain several years without the seeds being injured, especially where they are close.

They should be sown in the early spring months, as March or the following month, on beds of fine earth, in a north-east aspect, or in large pots or boxes for the purpose of being occasionally removed into different situations as may be found necessary. They should be covered with nets to prevent the birds from pecking off the tops of the young plants, while the husks of the seeds are upon them; and be likewise screened from the heat of the sun at first.

All the sorts, except the Stone Pine and a few others, the scales of the cones of which are very hard, soon come up; but these frequently remain more than a year: the ground should therefore not be disturbed, being only kept clean from weeds in such cases.

Soaking the seeds in these cases may be useful, as well as sowing them in shaded situations.

The young plants in all the sorts should be kept quite clean and occasionally refreshed with

water when the season is dry, in a very gentle manner, so as not to disturb the plants.

When they come up too close the plants should be thinned out in the summer, the thinnings being planted out immediately in a separate bed, in a shady place, being gently watered as there may be occasion. They should be set out in rows at the distance of four or five, and three or four in the rows. The tender kinds should be sheltered during the winter by frames or mats from the frosts, but with the others it is unnecessary.

When the plants have remained in these beds a year or more according to circumstances, they should be removed into other rows in the nursery at the distance of two feet, and one or more in the rows. In this situation they should remain till the periods of their being finally planted out.

The best season for the removal of the plants in all cases is towards the latter end of March or the beginning of the following month.

Where it can be done, it is the best way not to let them remain too long in these nursery situations, as the plants are always found to succeed best when planted out before they have acquired too large a growth.

When large plantations are to be made it is advised by some to raise the plants on a portion of the same ground, or as nearly similar to it as possible.

It is advantageous when they are to remain to have a large size to transplant them every two years, as by that means they form better roots and such as spread out more laterally, and of course the plants may be afterwards removed with greater safety.

In removing the plants, at all times great care should be taken to preserve the roots as much as possible, as well as all the branches, without cutting them.

When they have been finally removed, they require little more trouble, it being only necessary to keep them perfectly free from weeds, and supporting the larger sorts of plants with proper stakes: all the sorts should be suffered to take their own natural growth; being careful to preserve their tops perfectly entire, to shoot up as fast as possible and to branch out in their own way as no pruning is wanted, unless in the lowermost branches in particular trees which are thought too low and straggling, when these may be occasionally trimmed, cutting them close to the stem; but pruning should be very sparingly practised to these resinous trees, as lopping the branches contributes to retard their growth as well as impair their beauty. In large forest

plantations, where the trees are arrived to a large growth, it is however customary to lop their lower branches gradually for faggots, according as they begin to decay; for where these trees stand close, the upper branches generally kill those below, so that the lower tiers decay gradually and successively; in which case these decaying lower branches may be lopped by degrees in winter.

After the plantations designed for timber-trees have had eight, ten, or twelve years' growth, it may be proper to begin to thin them; those thinned out may serve for many smaller purposes, being careful in thinning to leave a sufficiency of the finest plants standing at proper distances to grow up for timber.

These trees are all highly ornamental evergreens for the pleasure-grounds.

In regard to the distribution or arrangement of the trees in the plantations, and mode of planting, those designed for the shrubbery and for ornamental plantations may be disposed both in assemblage with other trees, and to form clumps, and continued plantations. Those intended as forest-trees should generally be disposed alone in considerable plantations. The method of planting them is the same as in other hardy trees; but where large plantations in out-grounds are intended either for pleasure or profit, there will not be any great necessity for a previous preparation of the soil, with respect to digging or ploughing, only just to dig a hole for each tree: the same rule may also be observed in planting clumps of them in lawns, parks, and other grass-grounds, the mould being made fine in the bottoms of them. Those designed principally for ornament should be disposed at such distances as that their branches may extend freely every way; as the beautiful display of the head is a great merit in these trees in such plantations: but those intended for timber plantations may be put only four or five feet distant, in order that they may draw one another up straight and tall more expeditiously, and to admit of a gradual thinning after a few years' growth, for poles, &c.

The proper methods of raising and planting out all the different sorts, in the view of affording timber or shelter in large plantations, may be seen in the new edition of Miller's Dictionary.

PIPER, a genus containing plants of the herbaceous shrubby perennial exotic kinds.

It belongs to the class and order *Diandria Trigynia*, and ranks in the natural order of *Piperitæ*.

The characters are: that the calyx has no

perfect spathe: spadix filiform, quite simple, covered with florets: perianthium none: there is no corolla: the stamina have no filaments: anthers two, opposite, at the root of the germ, roundish: the pistillum has a larger ovate germ: style none: stigma threefold, hispid: the pericarpium is a roundish one-celled berry: the seed single, globular.

The species are: 1. *P. nigrum*, Black Pepper; 2. *P. Amalago*, Rough-leaved Pepper; 3. *P. longum*, Long Pepper; 4. *P. methysticum*, Intoxicating Pepper, or Ava; 5. *P. reticulatum*, Netted-leaved Pepper; 6. *P. aduncum*, Hooked-spiked Pepper; 7. *P. pellucidum*, Pellucid-leaved Pepper; 8. *P. obtusifolium*, Blunt-leaved Pepper.

The first has a shrubby, very long, round, smooth, jointed stem, swelling towards each joint, slender, branched, scandent or trailing, rooted at the joints: the leaves acuminate, quite entire, equal at the base, flattish, bent back a little at the top and edges, alternate, of a dark green colour, at the joints of the branches upon strong sheath-like footstalks: the flowers sessile, lateral, and terminating, in simple, longish spikes, opposite to the leaves: the berry globular, of a red brown colour. It grows in the East Indies and CochinChina.

Martyn observes, that "White Pepper was formerly thought to be a different species from the Black; but it is nothing more than the ripe berries deprived of their skin, by steeping them about a fortnight in water; after which they are dried in the sun. The berries, falling to the ground when over-ripe, lose their outer coat, and are sold as an inferior sort of White Pepper."

The second species is a shrub from three to ten feet in height: stem even: branches dichotomous, jointed, subdivided, round, brownish green: the leaves alternate, acuminate, not oblique, nerved and veined, very thin, bright green, smooth, paler underneath: the petioles round, smooth: the joints swelling: the spikes peduncled, opposite to the leaves, filiform, loose, many-flowered: the flowers clustered: the berry sessile, containing a single seed, double the size of hempseed, black when ripe, of a taste slightly pungent. It is a native of Jamaica and Hispaniola.

The third has the stems shrubby, round, smooth, branched, slender, climbing, but not to any considerable height: the leaves differing much in size and form; but commonly heart-shaped, pointed, entire, smooth, nerved, deep green, alternate: the flowers small, in short dense terminating spikes, which are nearly cy-

lindrical: the berries are very small, and lodged in a pulpy matter: like those of Black Pepper they are first green, and become red when ripe; they are hottest to the taste in the immature state, and are therefore gathered whilst green, and dried in the sun, when they change to a blackish or dark gray colour. It is a native of the East Indies.

The fourth species has a dichotomous stem, spotted, attaining the height of a fathom: the leaves oblong-cordate, not roundish-cordate: the spikes straight, short, solitary, and not aggregate, long, and nodding. It is a native of the islands of the South Seas.

It has the property of intoxicating when chewed.

The fifth is a shrub: the stem about five feet high, sending out several side branches which have protuberant joints: the leaves six inches long and five broad near their base; they have five veins springing from the footstalk, the middle one going in a direct line to the point; the two side veins diverge towards the edges of the leaves in the middle, but approach again at the top; the surface of the leaves is full of small veins, which form a sort of net-work: the spikes come out from the side of the branches opposite to the leaves; they are slender, and about five inches long, a little bending in the middle, and are closely set with very small herbaceous flowers. It is a native of Jamaica.

The sixth species has the stems several, shrubby, round, knobbed at the joints, smooth, an inch and more in thickness, branched, ash-coloured, upright, eight feet high: the branchlets green, the thickness of a quill, spreading very much: the leaves alternate, on short petioles, in a double row, a little shorter at the inner base, deep green above, rugged backwards, rough-haired when examined by a glass; underneath pale green, villous but not rugged; quite entire, netted with numerous veins, many-nerved if the principal veins be considered as nerves; they are about half a foot in length, and have little taste or smell: the stipule lanceolate, acute, converging, smooth, striated, caducous: the peduncles alternate, opposite to a leaf, solitary, erect, round, somewhat villous, half an inch long: the spikes solitary, slender, yellowish, two or three inches in length, towards the origin of the branchlet bowed, so closely covered with minute fructifications, that it is scarcely possible to detect their structure even with a microscope. It is called Spanish Elder in Jamaica, where it is a native.

The seventh is annual: the stalks are succulent, seven or eight inches high: the leaves an

inch and half long, and three quarters of an inch broad: the spikes of flowers come out at the end of the stalks, are slender, about an inch long, and straight: the flowers are very small, and sessile, appear in July, and are succeeded by very small berries, each containing a small seed like dust. It is a native of South America.

The eighth species sends out from the root many succulent herbaceous stalks almost as large as a man's little finger; they are jointed, and divide into many branches, never rising above a foot high, but generally spread near the ground, putting out roots at each joint, propagate very fast, and soon cover a large space of ground: the leaves are very thick and succulent; they are about three inches long and two broad, very smooth and entire: the peduncle comes out at the end of the branches; this is also very succulent, and the whole length, including the spike, is about seven inches: the spike is straight, erect, and about the size of a goose-quill, closely covered with small flowers which require a glass to be distinguished; the whole spike much resembles the tail of a lizard. It is a native of South America, flowering from April to September.

Culture.—All these plants may be increased by seeds, procured fresh from the countries where the plants grow naturally, which should be sown upon a good hot-bed in the spring, and when the plants come up and are fit to transplant, be each put into a separate small pot filled with light fresh earth, and replunged into a hot-bed of tanner's bark, shading them every day from the sun till they have taken fresh root, when they must be treated in the same way as other tender exotic plants, admitting fresh air to them daily in proportion to the warmth of the season, to prevent their drawing up weak; and when the nights are cold the glasses of the hot-bed should be covered with mats.

They all require the constant protection of a hot-house.

As the stalks of most of them are tender when young, they should not have much wet, which rots them; and when water is given it must be with caution, not to beat down the plants; for when that is the case they seldom rise again, afterwards.

In some of the sorts they may be raised from layers or cuttings.

In the after-management of the plants, they must be plunged into the tan-bed of the bark-stove in the autumn, and during the winter be sparingly watered: they require the same warmth as the Coffee-tree. In the summer a large

share of fresh air must be admitted in hot weather, and they must be constantly kept in the stove, as suggested above.

They afford ornament and variety in stove-collections.

PIPER. See CAPSICUM.

PIPER JAMAICA. See MYRTUS PIMENTA.

PIPERIDGE TREE. See BERBERIS.

PISCIDIA, a genus furnishing plants of the exotic tree kind.

It belongs to the class and order *Diadelphia Decandria*, and ranks in the natural order of *Papilionaceæ* or *Leguminosæ*.

The characters are: that the calyx is a one-leaved, bell-shaped, five-toothed perianthium: the upper teeth nearer: the corolla papilionaceous: banner ascending, emarginate: wings the length of the banner: keel crescent-shaped, ascending: the stamina have ten filaments, uniting in a sheath cloven above: anthers oblong, incumbent: the pistillum is a pedicelled gerin, compressed, linear: style filiform, ascending: stigma acute: the pericarpium is a pedicelled legume, linear, with four longitudinal membranaceous angles, one-celled, separated by doubled isthmuses: the seeds some, subcylindric.

The species are: 1. *P. Erythrina*, Jamaica Dogwood Tree; 2. *P. Carthaginensis*, Carthaginian Piscidia.

The first in its native situation rises with a stem to the height of twenty-five feet or more, almost as large as a man's body, covered with a light-coloured smooth bark, and sending out several branches at the top without order: the leaves are pinnate, with seven leaflets for the most part, two inches long, and one inch and a half broad, commonly opposite: the flowers of a dirty white colour, succeeded by oblong pods, which have four longitudinal wings, and are jointed between the cells. It is a native of Jamaica.

The second species differs from the first in the shape and consistence of the leaves, which are more oblong and of a firmer texture; in other respects they are very similar. It is a native of the West Indies.

Culture.—They are capable of being increased by seeds, when they can be obtained fresh from the countries where they grow naturally. They should be sown upon a good hot-bed in the spring, and when the plants come up and are fit to transplant, be each planted in a small pot filled with light earth, and plunged into a hot-bed of tanner's bark, and afterwards treated in the same way as the other tender exotics of the same kind.

They afford variety in the stove.

PISONIA, a genus containing plants of the exotic tree kind for the stove.

It belongs to the class and order *Polygamia Dioecia*, (*Heptandria Monogynia*), and ranks in the natural order of *Nictagineæ*.

The characters are: that in the male—the calyx is scarcely any: the corolla one-petalled, bell-shaped, five-cleft: segments acute, patulous: the stamina have five, six, or seven awl-shaped filaments: anthers roundish, twin: the pistillum is an oblong germ: style short: stigma pencil-shaped: female—the calyx and corolla as in the male: the pistillum is an oblong germ: style simple, cylindrical, longer than the corolla, erect: stigmas bifid: the pericarpium is an oval berry, often five-cornered, valveless, one-celled: the seed single, smooth, oblong.

The species is *P. aculeata*, Prickly Pisonia.

The male and female plants differ considerably.

The first has stalks as thick as a man's arm, which rise ten or twelve feet high: the bark is of a dark brown colour, and smooth; these send out many branches by pairs opposite, which are much stronger than those of the female, and do not hang about so loose: they are garnished with obovate stiff leaves, an inch and a half long, and an inch and a quarter broad, standing opposite, on short footstalks. From the side of the branches come out short spurs, like those of the Pear-tree, having each two pairs of small leaves at bottom, and from the top comes out the peduncle, which is slender, about half an inch long, dividing at the top into three; each of these sustains a small corymb of herbaceous yellow flowers, each having five stamina standing out beyond the petal, terminated by obtuse anthers.

In the female the stalks are not so strong as those of the male, of course require support. These rise eighteen or twenty feet high, sending out slender weak branches opposite, which are armed with short, strong, hooked spines, and have small oval leaves, about an inch and three quarters broad; these stand opposite on the larger branches, but on the smaller they are alternate, and have short footstalks: the flowers are produced in small bunches at the ends of the branches, sitting upon the germ; they are shaped like those of the male, but have no stamina; in the centre is situated a cylindrical style, crowned with five spreading stigmas: the germs afterwards turn to a channelled, five-cornered, glutinous capsule, armed with small crooked spines, each containing one oblong, oval, smooth seed. It is a native of Jamaica, where it is called *Cock's-spur*, or *Fingrigo*; and flowers in March and April.

Culture.—It is increased by seeds, which should be sown in pots filled with light rich earth, and plunged into a hot-bed of tanner's bark; and when the plants come up, they should be transplanted into separate pots, and plunged into the hot-bed again, where they may remain till autumn, when they should be removed into the stove, and plunged into the bark-bed, and treated in the same manner as has been directed for several tender plants of the same country; in hot weather giving them plenty of water, but in winter more sparingly.

They are too tender to thrive in the open air of this country at any season of the year, they should therefore be constantly kept in the stove. They retain their leaves most part of the year in this climate.

They afford variety in stove collections of exotic plants.

PISTACHIA NUT. See **PISTACIA.**

PISTACIA, a genus containing plants of the exotic deciduous tree and shrubby evergreen kinds.

It belongs to the class and order *Dioecia Pentandria*, and ranks in the natural order of *Amentaceæ*.

The characters are: that in the male—the calyx is a loose ament, scattered, compressed, of small one-flowered scalelets: perianthium proper, five-eleft, very small: there is no corolla: the stamina have five filaments, very small: anthers ovate, four-cornered, erect, patulous, large: female—the calyx ament none: perianthium trifid, very small: there is no corolla: the pistillum is an ovate germ, larger than the calyx; styles three, reflex: stigmas thickish, hispid: the pericarpium is a drupe dry, ovate: the seed is a nut ovate, smooth.

The species are: 1. *P. vera*, True Pistacia Tree; 2. *P. Terebinthus*, Common Turpentine Tree; 3. *P. Lentiscus*, Mastick Tree.

The first grows to the height of twenty-five or thirty feet; in its native situation the bark of the stem and old branches is of a dark russet colour, but that of the young branches is of a light brown: the leaves are composed of two or three pairs of leaflets terminated by an odd one; they approach towards an ovate shape, and their edges turn back. They emit an odour like that of the nut, when they are bruised. Some of the trees produce male flowers, others female; and some, when they are old, have both on the same tree. The male flowers come out from the side of the branches in loose bunches, and are of an herbaceous colour: the female flowers come out in the same manner in clusters. It is a native of Persia.

In the second species the situation of the buds is similar to that in the preceding species:

the leaflets seven, the middle ones for the most part larger, or the odd leaflet and the two inmost smaller than the four others; each ovate-oblong, by no means acuminate but styled, most of them also are wider on one side. It is by some described as a low shrub, but very thick: the wood is odorous and balsamic: the leaves have two pairs of leaflets, terminated by an odd one which is larger: they are firm, and shining on the upper surface: the flowers from branching catkins at the axils of the leaves, and are reddish. It is a native of Barbary and the South of Europe, flowering here in June and July.

The Cyprus or Chian Turpentine, which this tree furnishes, is procured by wounding the bark of the trunk in several places, during the month of July, leaving a space of about three inches between the wounds; from these the Turpentine is received on stones, upon which it becomes so much condensed by the coldness of the night, as to admit of being scraped off with a knife, which is always done before sun-rise: in order to free it from all extraneous admixture, it is again liquefied by the sun's heat, and passed through a strainer; it is then fit for use.

The third rises to the height of eighteen or twenty feet, the trunk being covered with a gray bark. It sends out many branches, which have a reddish brown bark: the leaves have three or four pairs of small leaflets, of a lucid green on their upper, but pale on their under side: the midrib has two narrow borders or wings running from one leaflet to another: the male flowers come out in loose clusters from the sides of the branches, are of an herbaceous colour, appear in May, and soon fall off; they are generally on different plants from the fruits, which also grow in clusters, and are small berries, of a black colour when ripe. It is a native of the South of Europe and the Levant.

There is a variety which rises to the same height as the preceding; but differs from it in having a pair or two of leaflets more to each leaf, much narrower and of a paler colour. It is a native of the country about Marseilles, &c.

Culture.—The first is capable of being increased by the seeds or nuts, procured from abroad and planted in the spring, in pots filled with light kitchen-garden earth, plunging them into a moderate hot-bed: when the plants appear, a large share of air should be admitted to them, to prevent their drawing up weak; and by degrees they should be hardened to bear the open air, to which they may be exposed from the beginning of June till autumn, when they should be placed under a hot-bed frame to screen them from the frost in winter; as while young, they are too tender to live through the winter in this climate.

without protection, but should always be exposed to the air in mild weather: they shed their leaves in autumn, and therefore should not have much wet in winter. In the spring, before the plants begin to shoot, they must be removed each into a separate small pot; and be plunged into a very moderate hot-bed, to forward their putting out new roots. As soon as they begin to shoot, they must be gradually hardened, and placed abroad again.

These plants may be kept in pots three or four years till they have got strength, during which time they should be sheltered in winter; and afterwards be turned out of the pots, and planted in the full ground, some against high walls to a warm aspect, and others in a sheltered situation, where they bear the cold of our ordinary winters very well, but in severe frosts are often liable to be destroyed. The trees flower and produce fruit, but the summers are seldom warm enough to ripen the nuts.

The third sort is also capable of being increased by laying down the young branches, which, if properly managed, put out roots in one year, and may be cut off from the old plants, and be planted out into separate small pots. These must be sheltered in winter, and in summer placed abroad in a sheltered situation, and treated in the same way as other hardy kinds of green-house plants.

When raised from seeds they should be taken from trees growing in the neighbourhood of the male plants, as otherwise they will not grow. When these plants have obtained strength, some of them may be turned out of the pots, and planted against warm walls; where, if their branches are trained against them, they endure ordinary winters very well, and with a little shelter in severe winters may be preserved with safety.

They are curious and ornamental in different situations.

- **PISUM**, a genus comprising plants of the hardy herbaceous kind.

It belongs to the class and order *Diadelphia Decandria*, and ranks in the natural order of *Papilionaceæ* or *Leguminosæ*.

The characters are: that the calyx is a one-leaved, five-cleft, acute, permanent perianthium: the two upper segments shorter: the corolla is papilionaceous: standard very broad, obcordate, reflex, emarginate with a point: wings two, roundish, converging, shorter than the standard: keel compressed, semilunar, shorter than the wings: stamina have diadelphous filaments; one simple, superior, flat, awl-shaped; and nine awl-shaped below the middle united into a

cylinder which is cloven at top: anthers roundish: the pistillum is an oblong, compressed germ: style ascending, triangular, membranaceous, keeled with the sides bent outwards: stigma growing to the upper angle, oblong, villose: the pericarpium is a large legume, long, roundish or compressed downwards, with the top acuminate upwards, one-celled, two-valved: the seeds several, globular.

The species are: 1. *P. sativum*, Common Pea; 2. *P. maritimum*, Sea Pea; 3. *P. Ochrus*, Yellow-flowered Pea.

The first has an annual, slender, fibrous root: the stems hollow whilst young, brittle, branched, smooth, weak, climbing by terminating tendrils: leaves abruptly pinnate, composed usually of two pairs of leaflets, which are oval and smooth: the stipules large, surrounding the stem or branch: the flowers lateral, two or three together on long peduncles: the corolla white, greenish white, purple or variegated: the legumes commonly in pairs, about two inches long, of an oblong form, smooth, swelling at the straight suture, where the seeds are fastened, flattened next the other suture, which arches, especially towards the end: the seeds from five or six to eight or nine, commonly globular, but in some varieties irregular or approaching to a cubic form, smooth, white, yellow, blue, gray, brown, or greenish, with a small oblong umbilicus: the colour of the whole plant is glaucous, or hoary green, from a white meal which covers it. It is said to be a native of the South of Europe.

There are two principal varieties, the white and gray; and several sub-varieties, the principal of which are:

Early kinds.—The Early Golden Hotspur; Early Charlton Hotspur; Nichols's Early Golden Hotspur; the Early Charlton; the Reading Hotspur; Masters's Hotspur; Ormrod's Hotspur; Early Dwarf Hotspur; Leadman's Dwarf; Fan Spanish Dwarf; Early Dwarf Frame Pea; Pearl Pea; Cluster Pea; Royal Green Pea; Essex Hotspur; the Dwarf Pea; the Sugar Pea.

Late kinds.—Spanish Morotto; Nonpareil; Sugar Dwarf; Sickle Pea; Marrowfat; Dwarf Marrowfat; Rose or Crown Pea; Rouncival Pea; Gray Pea; Large Gray Pea; Crooked Gray Pea; Long-bearing Pea; Green Field Pea; White Field Pea; Pig Pea.

Many of the first sub-varieties are very early, and, being low growers, require sticks of three or four feet only in height, and often not so much. New varieties of these are raised almost every year, which, because they differ in some

slight particular, are sold at an advanced price, and have frequently the names of the persons who raised them, or the place where they first grew. These varieties are not permanent, and without the greatest care will soon degenerate.

The second species has a perennial root, running far and deep among the stones or into the sand in every direction: the stems are procumbent, quadrangular, a little compressed, striated, smooth, leafy, many-flowered, glaucous, often reddish: the leaves alternate, alternately and abruptly pinnate, spreading: the leaflets sessile, oval, obtuse with a little point, entire, smooth, many-veined, glaucous; common footstalk flatish, striated, ending in a branched thread-shaped smooth tendril: the stipules two together, equal, acute, toothed at the base, of the texture and colour of the leaflets, but smaller: the clusters of flowers axillary, solitary, as long as the leaves, erect, many-flowered: the common peduncle round, striated, smooth: pedicels alternate, short, single-flowered: the flowers rather large, a little drooping: the corolla beautifully variegated with red and purple.

According to Mr. Woodward, the stems are slightly pubescent and short: leaves numerous: leaf-stalks angular, pubescent: leaflets alternate, on the lower leaves five or seven, upwards nine or eleven; there being always one more on the lower than on the upper side of the leaf-stalk, which is terminated by a tendril, sometimes simple, but oftener bifid at the extremity: stipules oval-lanceolate, broad, arrow-shaped at the base: flowers crowded on the summit of the naked peduncle: pods long and narrow.

It is remarked by Dr. Smith, that this species is almost as nearly allied to *Lathyrus* as to *Pisum*, both in habit and generic character; and that *Pisum sativum* is not more different in external appearance from the genus of *Lathyrus*, than *Vicia Faba* or the Bean is from the other *Viciæ*. These, however, he adds, are matters of opinion: and in so natural a class, it is very difficult to find out certain and obvious marks of distinction. It is a native of the sea-shores of Europe, &c.

The third has an annual root: the stalk is angular, near three feet high: the leaves on winged footstalks, each sustaining two oblong leaflets: the flowers are pale yellow, and small: the pods two inches long; containing five or six roundish seeds, a little compressed on their sides; these may be eaten green, but unless they are gathered very young, they are coarse, and at best not so good as the common Pea. It is a native of the South of Europe, and of the Levant. It flowers in June and July.

Culture in the open Ground.—All the sorts of the first kind are raised from seed, sown annually; and as those of one sowing continue but a short time in bearing, several sowings are requisite each season, to continue successions for the table all summer; each sowing to remain where sown, choosing a warm dry border, &c. for the earliest crops; and for the succeeding ones, any of the common quarters, in a free exposure, distant from the shade of trees, &c., but open to the sun.

For the late crops the more moist parts are the best.

The general season for sowing is any time in open weather, from the latter end of October, or in November, until May or June.

But in order to have green Peas as early as possible, recourse must be had to the assistance of hot-beds, by the aid of which they are obtained in March and April, and continued till the coming in of the natural ground crops, in the latter end of May or beginning of the following month.

The early and first general Crops.—Towards the latter end of October, in November or December, as the weather may be convenient, the earliest crops should be put into the ground. In warm soils and situations it is always advisable to sow a few in the two former months; but in general, and especially in open exposed grounds, November and December is time enough to begin the principal sowings. For this purpose the Earliest Charlton or Golden Hotspurs are the most proper.

And in order for their reception a warm south border, or some other dry, sheltered, sunny situation should be dug over and prepared; when, in a dry day, drills should be drawn by a line, ranging south and north, to enjoy the greater advantage of the sun's influence, making them an inch and a half deep, and two feet and a half at least asunder; but if designed for sticks, three feet and a half will be a more proper distance. Then the seed should be scattered in evenly along the middle of each drill, rather thickish, as they are liable to accidents from vermin and the season, covering them in regularly with the earth either with a rake or hoe, being careful that they are all equally covered the depth of the drills; and then with a rake lightly trim the surface smooth; which finishes the work.

The peas begin to germinate in a fortnight, if mild weather, and come up in three weeks or a month, but seldom in less time at this season; when the plants are to be managed as directed below.

Another sowing should be performed in three weeks or a month after this; or when the first was sowed in October or early in the following month, it is better to repeat the sowing in a fortnight or three weeks, for fear the first should fail; and after this continue sowing once in three weeks or a month all winter in mild weather. But towards spring a principal crop of the Reading and other large Hotspurs should be sown; and as the season advances, the sowings be made in more open exposures, and more in quantity than the early ones; and as the spring draws on, the sowings should also be repeated oftener; as from the close of the year till the beginning of April, they should be once in three weeks; and from that time till May, once a fortnight, especially as the warm weather increases.

The winter and early spring sowings differ materially in the time they require to germinate: those sown any time in winter are sometimes three weeks or near a month before they appear, while those sown towards spring come up much sooner in the later spring sowings, often in a very short time.

In the later of the above sowings, some of the dwarf sorts may be introduced; as Leadman's Dwarf, both for middle and late crops.

As the plants of each sowing come up, and are advanced two or three inches in height, it is proper to begin the first culture by drawing a little earth with a hoe, or small rake, lightly up to their stems on each side of the different rows to strengthen and forward their growth; repeating the earthing once or twice at proper intervals, as occasion may require, and at the same time cutting up and clearing away all weeds; and when the crops are six or eight inches in height, those designed for support should be sticked.

As the earliest crops are often in danger from the severity of frosts, it is proper, when they are about an inch or an inch and a half high, to draw a little fine earth lightly up to their stems in a dry day; it will also be of much advantage to give occasional protection to such crops in severe weather, by covering them lightly with long, light, dry litter, of the strawy kind, or by mats; which, where there is but a moderate quantity in warm borders, may be more easily effected; but this need only be practised in very severe frosts. They must however be carefully uncovered every fine day in temperate weather; and the moment the frost disappears the covering be entirely removed; as they must by no means be kept too close, which would draw them up weak and tender.

When in blossom, if the weather should prove dry and warm, a few good waterings in the mornings will be beneficial; and when the blossoming plants are advanced a considerable height, if they are then topped, it will promote their podding and coming to perfection.

As to the succeeding crops of the different kinds, all they require is hoeing up the earth to their stems occasionally, and cutting up all weeds when they appear; those designed for support being always sticked as soon as they are half a foot high, or a little more, before they begin to fall down on their sides, providing sticks about four or five feet long, and placing one range to each row principally on the south or most sunny side of the rows, as the plants naturally incline towards the sun, and of course more readily attach themselves to the sticks.

In the culture of the larger kinds, for successional general crops, such as the Marrowfats; Spanish Morattos; &c.; they may be begun sowing in January, the Dwarf Marrowfats first; but the three following months are the most proper for the general crops of all the large kinds; a free exposure in the most open quarters being made use of, drawing drills by line, about an inch and a half or two inches deep, and not less than a yard asunder, and when sticked, four feet, and for the largest sorts four feet and a half to five feet, in single or double rows.

In these cases the seed should be sown thinly along the middle of each drill, drawing the earth evenly over them with the rake, hoe, or feet, covering them equally the depth of the drills, and raking the surface smooth; these sowings being repeated once a fortnight or three weeks; and as the spring advances, once a fortnight, especially from the beginning of April until the end of the following month. Afterwards a few may be sown every ten or twelve days. Late sowings are, however, seldom very fruitful, being often attacked with the mildew; but it is proper to endeavour to have some as long in the season as possible.

When these different crops are come up about three inches high, they should have earth laid up to them on each side of the rows, cutting down all weeds, and repeating the hoeings occasionally according as the growth of weeds may require; and when they are half a foot, or eight or ten inches high, they should have the sticks placed to them; which for these large sorts require sticks six or seven feet high, at least, placing them on the sunny side of the rows, as directed above.

For late crops, any of the sorts, either Hot-

spurs or larger kinds, may be continued sowing all May and until the middle or latter end of June; likewise some of the dwarf sorts at a later period for late production. It may be proper to sow larger portions of Roundvals for the latest crops, on account of their being rather the hardiest to struggle with the summer's heat and drought, and thereby most to be depended on for a late production.

For these crops some of the moistest ground should be chosen; and if the weather should prove very dry and hot, it will be of importance to soak the seed in soft water six or eight hours previous to sowing; or the drills may be well watered after it has been done; either of which will promote their rising expeditiously and more regularly.

It may be observed, in respect to the times of sowing, that it is a good rule, in the different sorts, as soon as one crop appears fairly above ground, to sow another to succeed it of the same kind, so as to have a regular succession of crops following one another in bearing; and if a crop of Marrowfats, &c., and another of Hotspurs, be sown on the same day, the Hotspurs will come into bearing a fortnight the soonest, and the Marrowfats will arrive to a bearing state about the time the others are going out, just in due time to succeed them; which should be attended to in order to have these sorts form a regular succession to each other.

In gathering the crops, both hands ought always to be employed; one to hold the peduncle or footstalk of the fruit, while the other pulls the pods; otherwise the stem or main stalk of the plant, being slender, fragile, and weak, is liable to be broken and destroyed; and the gatherings should always be regularly performed according as the pods fill, never letting them stand to grow old, as they are in the greatest perfection for eating while green, and the plants continue longer in bearing. Crops of peas continue only about a fortnight in full bearing, during which time they furnish a plentiful gathering of pods in their perfection; though in moist showery weather they sometimes continue shooting and flowering three or four weeks; but the produce after the first fortnight is generally inferior both in quantity and quality.

As soon as the crops are past bearing, all the sticks should be taken up and tied in bundles, being set upright in any dry corner for future use.

Culture in Hot-beds.—In order to have green Peas as early in the year as possible, recourse must be had to the assistance of hot-beds; and the proper sorts for this purpose are

the early dwarf kinds, which by this means may be brought into bearing in March, or the following month.

In this intention it is rather the best mode to raise the plants first in the natural ground, by sowing in October or the following month, giving occasional protection from frost; and when one or two inches high, to transplant them into the hot-bed, in January or the beginning of the following month, as by this practice the luxuriant growth of the plants is so checked by the removal, that they shoot more moderately, and thereby blossom and bear sooner and more abundantly.

The sowings should be performed in a warm, dry, south border, or in some similar dry sheltered part of light good earth, in a bed of proper dimensions to have the protection of a frame, &c., in severe weather; sowing them in drills about a foot asunder, in the manner as for the common crops: when they are come up and advanced a little in growth, in a dry day some fine earth should be drawn up to their stems, giving suitable protection in bad weather.

But they may be sown on a moderate hot-bed in December or January, under frames, &c., and when the plants are up, plenty of free air should be admitted every temperate day, and be defended in the nights from frost, snow, and cutting cold; or some may be sown in large pots, and be placed in a hot-house, &c., to bring up the plants quickly for transplanting into the intended hot-bed in January. And they may be sown at once in a hot-bed at the above periods, to remain for bearing: but it is generally more eligible to have the plants previously raised an inch or two in height, either by early sowing in the full ground, or forwarded under frames, or in a hot-bed, &c., as above, for transplanting into a fresh-made hot-bed for bearing.

In either of the above methods of raising the plants for transplanting, when advanced from one to two inches in growth, or little more, they are proper for planting out into the hot-bed to remain for fruiting.

In mild weather, towards the middle or latter end of January, or the beginning of the following month, at furthest, a hot-bed for one or more of the largest three-light frames and glasses should be prepared, which may be either of dung or tan; the latter, where it can be obtained easily at a moderate expense, is considerably the best for this purpose. It should be made two feet and a half or a yard thick, and covered with frames and lights, and when in a moderate temperature the earth be put on for the reception of the plants. Any light good dry earth

may be employed, which should be laid eight or ten inches thick all over the bed; then in a dry mild day the plants may be taken up, raising them with their roots as entire as possible, with what earth will readily hang about the fibres; and after drawing small drills in the earth of the hot-bed, from the back to the front of the frame, a foot and a half asunder, and about an inch deep, the plants should be put in the drills, not more than an inch apart, covering in the earth close to their roots and stems, and giving a very light watering, just to settle the earth; after which the lights should be put on; being careful to raise them occasionally at the upper end to give vent to the steam, &c.: and at first planting out, when in sunny weather, if the plants should flag, a moderate shade should be given in the middle of the day, till the plants have taken root and established themselves.

After this, fresh air must be admitted to the plants daily in fine weather to strengthen them, by tilting the upper end of the lights according to the temperature of the bed and outward air; keeping them close in cold nights, and covering also with mats: occasional moderate waterings should likewise be given in fine days, and, as the plants advance in growth, a little earth be drawn up to their stems once or twice; repeating the moderate refreshments of water frequently as the warm season advances; which may be given more freely when the plants are in bloom. And according to the advanced growth of the plants and increased warmth of the weather, a larger share of fresh air in proportion should be given; and when they are in blossom, if the sun at any time appears too violent for them through the glasses, it is advisable to give a very slight shade an hour or two in the heat of sunny days; likewise, when in full blossom and fruiting, to admit plenty of free air, even sometimes in fine days shoving the glasses entirely off; also still continuing the waterings more abundantly during the time of setting and growth of the pods, and indulging them with the benefit of warm showers of rain. In this way the plants may be brought to bearing in March or April; and by a succession of two crops, in hot-beds made at three or four weeks' interval, and managed as above, a supply be continued till the natural ground crops come into bearing in May.

Where there is the convenience of fruit forcing-houses, hot-walls, &c. a few of the earliest kinds, either previously raised in young plants an inch or two in growth, as in the hot-bed culture, or in default of it, the seed sown; and which being in pots, are placed in these departments; or where there are internal borders of

VOL. II.

earth, some young plants may be placed therein. The internal moderate heat of the above departments, effected either by bark-beds, &c. or fire, or both occasionally, in a requisite degree for forcing the fruit-trees to early production, forwards the malso, so as to have some for gathering in the most early season, in a small proportion.

Culture in the Field.—Where designed to raise crops in order to gather the produce green and young for the supply of markets, November, or rather December, is soon enough to begin the first sowings, especially in open exposed grounds; a dry light soil being chosen for the more forward sowings. As to the sorts, any of the Hotspurs may be used for the forward crops, and for a general crop the Reading Hotspur is excellent; and after that sort, the Masters's and Ormrod's, &c. but of the large kinds the Marrowfat and Spanish Moratto should be chosen for the main crops.

The ground for their reception must be prepared by proper ploughing and harrowing; drills are then to be drawn with a hoe crossways the lands, or with a drill-plough lengthways, two feet at least, or two and a half asunder for the early and three for the larger sorts. As no sticks are intended for these large field crops, having sown the seed, it should be covered in either with the hoe, rake, or harrow; but the hoe or rake will cover them more evenly, and almost as expeditiously. When they come up they must be kept clean from weeds, by broad-hoeing; but this is sometimes performed in fields by horse-hoeing for the sake of expedition; which, having hoes fixed in a sort of plough horizontally, is drawn by a horse between the rows, a man holding the plough-shafts to guide it: but as this can only cut down the weeds, a common drawing hand-hoe must be used to earth up the plants: though this is often disregarded in the field-culture, it however proves very beneficial to the crops.

In these cases the rows should be laid down so as to face the sun as much as possible.

Saving Seed.—In order to save seed, some of each sort should be suffered to stand entirely for that purpose, or some sown of each purposely in different parts, and the whole produce suffered to remain and ripen for seed.

In the latter mode they should be sown in February in some open ground, in rows two or three feet asunder, no sticks being required, and, when the plants come up, be kept clean from weeds by hoeing, the earth being laid up to their stems once or twice. When they are in bloom, they should be examined row by row, to see if there be any degenerate sort, which, when present, must be pulled out; or if any improved

2 II

variety be discovered, to mark it; which is the only method to preserve both the purity of the known sorts, and to procure new varieties. For example, if amongst the Hotspurs any large sorts appear, they should be removed directly; also any Hotspurs, &c., from amongst the large kinds, and different sorts of any of these from each other; and if any new sort discovers itself either by flowering earlier than all the rest, or possessing some other singularity, or noticeable merit for culture, it should be carefully marked, the seed being saved separate, to sow separately for furnishing a proper increase.

According as the seeds of the different sorts ripen in July and August, which is discoverable by the pods changing brown, and the seed becoming a little hard, the haum should be cut or pulled up in dry weather, and exposed in heaps in the sun, turning them every day; and when the seed is become perfectly dry and hard, it may either be threshed out directly, or stacked up in a dry situation till another opportunity: but when threshed, each sort must be kept separate, and when properly cleaned be put up in sacks with the name of each upon them.

PLANE TREE. See PLATANUS.

PLANTAIN TREE. See HELICONIA.

PLANTATION, a large collection of different sorts of trees, planted out either for ornament, or the advantage of the wood as timber, or for both purposes.

Plantations of these kinds not only afford great improvement to estates, but are highly ornamental to the country. They should therefore be more particularly attended to where there are large tracts of poor barren lands that cannot be converted to the more profitable purposes of tillage or grass.

They have also a fine effect in the vicinity of habitations and pleasure-grounds. And in many cases the proprietors of estates, whether of large or moderate sizes, may reap great pleasure and advantage in allotting a part of them to this use, as they give grandeur as well as an air of fertility; and, after the first eight or ten years, in many cases bring in great profit by the gradual thinning of the underwood, besides leaving a sufficiency of standards to attain full growth.

The expense attending the making of Plantations, and the knowing that they must wait several years before the trees have made any considerable progress, or can afford any advantage, often prove an obstacle in attempting the prosecution of the business; but the expense of planting where the plants are raised on the grounds, will not be so great as may be imagined, especially as a small spot of nursery-ground will raise plants enough in three or four years,

to plant a great many acres of land, and the expense of raising and planting, with the loss of time in waiting until the plants attain some growth, will be compensated by the first fall or thinning, in eight or ten years after planting; and the stools which remain shoot up again, in many of the deciduous kinds, and afford a lopping every eight or ten years, exclusively of the due portion of standards left at proper distances, to attain full growth for timber.

In making Plantations, it is necessary to choose such trees as are the best adapted to the nature of the particular soil and situation.

As to the proper sorts of trees or shrubs, most of the deciduous and ever-green kinds may be employed with propriety, and young plants, of from about two or three to five or ten feet in height, always prove more successful than such as are older; for although some, from their being in haste to have Plantations as forward as possible, transplant tall trees, perhaps twelve or fifteen feet high or more, especially for those of the ornamental kind; those of younger growth always take root sooner, and establish themselves more firmly, so as to form considerably the finest Plantations at last, and are of longest duration: for though large trees of from fifteen to twenty feet in height, especially of the deciduous kind, may with care be transplanted, so as to grow, and probably thrive tolerably for some years, yet by not rooting firmly like young plants, they often fail, and after some years standing have hardly made any shoots, and at last gradually dwindle and perish. Large trees should of course never be employed except on particular occasions, where a few may be necessary to form an immediate shade or blind, &c. in some particular place: but for general work, young plants, either raised, or purchased from the nurseries, should be made use of. And for principal Timber Plantations in particular, such plants as are only from about two or three, to five or six feet in height, or eight or ten at most, must be employed, having those of the same Plantation, as nearly of equal growth as possible. See PLANTING.

Where Plantations are intended principally for ornament, as great a variety as possible of the different sorts of hardy trees and shrubs should be employed, and should consist of lofty and middling growing trees, as well as of shrubs. See DECIDUOUS and EVER-GREEN TREES.

In regard to the disposition of the plants, the deciduous and ever-green kinds may be planted in separate compartments, or in mixture, and sometimes the tree-kinds by themselves, some in running varying Plantations,

towards the boundaries of lawns, parks, paddocks, &c. others in avenues, groves, thickets, and clumps, variously disposed in different parts; and sometimes the trees and shrubs together, forming shrubberies, wildernesses, shady walks, and wood-works; placing those of taller growth backward, and the lower in front; bordering the whole with the most beautiful flowering shrubs and showy ever-greens, especially next the principal walks and lawns, varying the form of all the several compartments, sometimes by moderate sweeps and curves outward and inward, of different dimensions, other parts in long easy bends, varied projections and breaks, so as to diversify the scene in imitation of natural Plantations. The proper distances, in planting, may be from five or ten to fifteen or twenty feet: for example, the tall trees designed for continued Plantations may be from ten to fifteen or twenty feet, varying the distance in different parts, according to light and shade, &c. and those in groves, where open may be fifteen or twenty feet distance, and where close ten or twelve; for thickets, five or six feet, or closer in particular places where a very dark shade or thick coverture of wood is required; and in clumps of trees, from five or ten to twenty feet between the trees in each clump, varying the distance occasionally, according to growth, as also the sorts and numbers of trees in each, from two or three, to five, ten, or more. The form of the clumps may sometimes be triangular, at other times quadrangular, pentangular, &c. and some in curves, others in straight lines, to cause the greater variety. And in shrubbery clumps, and wilderness compartments, where the trees and shrubs are employed promiscuously, they may be planted from five to ten feet distance; the taller growths being placed backward eight or ten feet asunder, placing the lower plants gradually forward according to their gradations, to the lowest in front, as above, at four or five feet distance: and if the trees and shrubs of the plantations in general are disposed somewhat in the quincunx way, they appear to the greater advantage, and produce a better effect.

But when large Plantations are to be formed into woods, &c. composed principally of forest and timber trees for profit, particular sorts must be chosen, consisting of deciduous and ever-green trees. Of the first kinds the oak, elm, ash, beech, chesnut, hornbeam, birch, alder, maple, sycamore, plane, poplar, lime, walnut, wild cherry, mountain-ash, larch, willow, hazel, &c. and of the latter sort, the pine, fir, cedar of Lebanon, holly, bay, laurel, yew, ever-green oak, box tree, and some others. See FOREST TREES.

In forming woods, or Plantations of timber-trees, there are two methods chiefly practised: one is by raising the trees from seed at once on the ground where the Plantation is intended to be, especially the deciduous kind, and which is effected by sowing the seed in drills, a yard asunder, the plants remaining where raised, thinning them gradually: the other method is by previously raising the plants in a nursery, till two or three feet high, then transplanting them into the places allotted them, in rows at the above distance, to allow also for gradually thinning. Either of these methods may be practised, as most convenient; but the former, or that of raising the plants where they are to remain, though it may be more expeditious, and at once gets rid of the trouble of transplanting, will require greater attendance for a few years, till the plants have shot up out of the way of weeds; but the trees, from their always remaining where raised, without being disturbed by removal, may probably make a greater progress. The latter method, or that of raising the trees first in a nursery, is rather the most commonly practised, as being thought the least troublesome and expensive, with regard to the attendance at first of the young growth.

The preparation of the ground for the final reception of the seed or plants, is mostly performed by deep ploughing and harrowing, upon such ground as the plough can be employed on; but, where this or other tillage is not practicable, only young plants from the nursery can be used, digging holes, &c. at proper distances, one for the reception of each plant: where, however, the ground can be tilled, it will prove very advantageous by performing it a year before; sowing it with a crop of turnips, or others of a similar kind; and when these come off, ploughing and harrowing the ground again, for the reception either of the seed or plants the ensuing season.

The most proper season for performing this sort of planting, either by seed or plants, is any time in dry mild weather, in the autumn, as from October till February, or later on moist soils. Where large tracts are to be planted, both the seed and plant methods must be pursued all winter, at every favourable opportunity.

The seeds may be put in, in furrows or drills one to two or three inches deep, and three or four feet asunder, scattering them along the middle of the drills, and covering the earth evenly over them, the depth of the drills or furrows; but sometimes the seeds are scattered or sown promiscuously over the general surface, and harrowed into the ground, being well protected from birds and vermin.

Where young plants are employed, they should be planted out in rows, three or four feet asunder, as directed for the seed, and one or two feet apart in the lines; they may be planted either by opening small apertures or holes with the spade for each plant; or, if very small plants, it is sometimes performed by making only a slit or crevice with the spade for each plant; and sometimes by opening or forming small trenches the whole length, then inserting the plants, one person holding whilst another trims in the earth about their roots; some again, in very large tracts, where the situation admits of previous ploughing and harrowing to divide and break the earth into small particles, open furrows with the plough, two or more persons being employed in depositing the trees in the furrow, whilst the plough following immediately with another furrow covers the roots of the plants with the earth, and afterwards treading each row upright. See PLANTING.

The grounds where the Plantations are made should be previously well fenced in all round with a deep ditch, &c. to guard against the encroachments of cattle or other animals.

In the after management, while the Plantations are young, they must have some attendance to destroy weeds, which may be expeditiously executed by hoeing between the rows in dry weather, or occasionally by horse-hoeing; and this care will be needful for two or three years, especially to the seedling plantations, until the trees are advanced out of the reach of weeds; after which no further trouble will be required until the trees are ready for the first fall or thinning, for poles, faggots, &c.

After eight or ten years growth, they are mostly of a proper size to begin the first fall by a moderate thinning, which will serve for poles and faggot-wood, to repay some of the expense of planting, &c. But only part of the Plantation should be lopped the first year; thinning out the weakest and most unpromising growth first; leaving a sufficiency of the most vigorous plants pretty close, to grow up for larger purposes; the year following thinning another part, and so continue an annual thinning-fall till the whole Plantation has been gone over; cutting each fall down near the ground, leaving the stools to shoot out again, especially in the deciduous kinds; and by the time the last fall has been made, the first will have shot up, and be ready to be cut again. So the returns of fallings may be contrived to be every six, seven, eight, or ten years, or more, according to the uses the poles or wood are wanted for: and if larger poles, &c. are wanted, the fall may be only once in fourteen, eighteen, or twenty

years, still, at every fall, being careful to leave enough of the most thriving plants for standards; being left pretty close at first, that they may mutually draw each other up in height; but thinned out every succeeding fall as they increase in bulk and meet, so as to leave a sufficient quantity of the principal trees at proper distances to grow up to timber, which in their turn, as they become fit for the purposes intended, may also be felled according as there may be a demand for them, to the most advantage; having young ones from the stools coming up in proper succession as substitutes, so as the ground may be always occupied as completely as possible.

PLANTING, the operation of inserting plants, seeds, and roots, into the earth, for the purpose of vegetation and future growth.

There are various methods of performing this business in practice for different sorts of plants, seeds, and roots; as Hole Planting; Trench Planting; Trenching-in Planting; Slit or Crevice Planting; Holing-in Planting; Drill Planting; Bedding-in Planting; Furrow Planting; Dibble Planting; Trowel Planting; Planting with balls of earth about the root; Planting in pots, &c. all of which are occasionally used by different practitioners in the several branches of gardening, according as the methods are most proper for different particular sorts of plants.

In the first, or *Hole Planting*, which is the principal method practised with most sorts of trees and shrubs in the full ground, and which is performed by opening with a spade round holes in the earth, at proper distances, for the reception of the plants, each hole should be dug large enough to admit all the roots of the tree or shrub freely every way to their full spread, without touching the sides of the hole, and about one spade deep, or a little more or less, according to the size of the roots and nature of soil, so as, when planted, the uppermost ones may be only about three or four inches below the common surface, or as low as they were before in the ground; though in very humid soils, where the water is apt to stand, the holes should be shallower, so as the uppermost roots may stand full as high as the general level, or higher if necessary, raising the ground about them, especially when performed in winter. When the soil has been thus dug out, the bottoms should be well loosened; the mould in digging out being laid in a heap close to the edge, in order to be ready to fill in again: the holes being thus prepared, and having slightly trimmed the roots, &c. of the trees, one tree or plant must be placed in the middle of the hole, making all its roots spread equally around;

a person holding the plant erect by the stem, while another with his spade casts in the earth about the roots, taking particular care to break all large clods, and trim in some of the finest mould first all round about the roots in general, shaking the tree occasionally, to cause the fine soil to fall in close among all the small root fibres; and where the tree stands too deep, shake it up gently to the proper height; and having filled in the earth to the top of the hole, it should be trodden gently all round, first round the outside to settle the earth close to the extreme roots, continuing the treading gradually towards the stem, to which the mould should be pressed moderately firm, but no-where too hard, only just to settle the earth, and steady the plant in an upright position: then all the remaining earth should be pared in evenly round the tree, to the width of the hole, raising it somewhat above the general level of the ground, to allow for settling, giving it also a gentle treading; and finishing it off a little hollow at top, the better to receive and retain the moisture from rains, and giving occasional waterings in spring and summer, especially for the choicer kinds of trees and shrubs.

After this, in winter, or late in spring, it may be of advantage to the choicer kinds of trees and shrubs, to lay some long mulch at top of all the earth, both to keep out the winter's frost, and prevent the drying winds and drought of spring and summer from penetrating to the roots before the trees are well rooted in their new situations. But some, instead of mulch, use grass turfs turned upside down, especially when planting upon grass ground, or any out-plantations where turfs of grass can be obtained; or in orchards, where the ground is in grass; in which case it may be proper to bank some turfs round the sides and top of each hole, particularly for large trees; which will steady them more effectually, as well as preserve the moisture, if much dry weather should happen the succeeding summer.

In the second, or Trench Planting, which is a method sometimes practised in the nursery, in putting out seedling and other small trees and shrubs in rows; and also used for box edgings, as well as sometimes for small hedge-sets, &c. and always in setting out Asparagus; it is performed by opening a long narrow trench with a spade, making one side upright, then placing the plants against the upright side, and turning the earth in upon their roots. When used for young seedlings, or other small trees, shrubs, &c. the ground is previously trenched or dug over: a line is then set, and with a spade held with its back towards the line, a narrow

trench six or eight inches deep is cut out, turning the earth from the line, making the line side nearly perpendicular: the plants are then inserted in the trench at small distances, close to the upright side, covering in the earth about the roots in planting them: and having planted one row, the earth should be evenly trodden in all the way along, to settle it close, and fix the plants steady, proceeding from row to row in the same manner.

But in planting larger trees in the nursery way by this method, a larger trench will be requisite: sometimes a trench one or two spades wide, with proportionable depth, according as the roots of the trees require, is made; and having opened it all the way along the intended row, the trees are placed along the middle of the trench, filling in some earth to each tree as placed, one person holding it erect whilst another throws in the earth; and having placed one row, trim in all the remaining earth evenly; then treading it closely all the way to fix the plants steady and in a perfectly upright manner.

In the third, or Trenching-in Planting, which is also sometimes practised in light pliable-working ground, for young trees in the nursery way, and sometimes with hedge-sets, &c. being performed by digging along by a line, about one spade in width, and planting at the same time; a line is set; and then having the plants ready, with a spade begun at one end, and standing side-ways to the line, throw out a spit or two of earth; which forming a small aperture, another person being ready with the plants, he directly deposits one in the opening, while the digger proceeds with the digging one spade wide, covering the roots of the plants with the earth of the next spit; and another aperture being thus formed, another plant is placed in: the digger, still proceeding, covers its roots, as before, with the next spit of earth; and so on to the end of the row, placing them at about a foot, or fifteen or eighteen inches asunder, according to the size of the plants. When larger trees with more spreading roots are used, instead of digging the trench only one spade wide, two may probably be requisite for the proper reception of the roots; likewise, in forming the openings for the plants, they should be made large enough to receive the roots freely, digging the earth over them as above. After having planted one row of plants, the earth should be trodden evenly along to settle it to the roots, and steady the plants in an upright position. There is another method of this sort of planting sometimes used for some sorts of roots, such as horse-radish sets, potatoes, &c. which is performed by common

trenching, placing a row of sets in each trench. The horse-radish should be planted in the bottom of the open trench, twelve inches in depth, turning the earth of the next over them; and the potatoe-sets be placed about from four to five or six inches deep, covering them also with the earth of the next trench.

In the fourth mode, or that of Slit Planting, which is performed by making slits or crevices with a spade in the ground, at particular distances, for the reception of small trees and shrub plants, a slit is made for each plant, which is inserted as the work proceeds; and is practised sometimes in the nursery-way, &c., in putting out rows of small plants, suckers, &c., at from about a foot to eighteen inches or two feet high, and which have but small roots: it is also sometimes practised in out grounds, where large tracts of forest-trees are planted, and which are planted out at the above sizes, and in the most expeditious and cheapest method.

It is performed in this manner: a line is set, or a mark made; and then having a quantity of plants ready, they are planted as the work proceeds in making the slits: a man, having a good clean spade, strikes it into the ground with its back close to the line or mark, forming a crevice, taking it out again directly, so as to leave the slit open, giving another stroke at right angles with the first; then the person with the plants inserts one immediately into the second-made crevice, bringing it up close to the first; and directly presses the earth close to the plant with the foot; proceeding in the same manner to insert another plant; and so on till all is finished: which is a very expeditious way of putting out small plants, for large plantations, but should never be employed where other better methods can be used.

A man and a boy in this method will plant out ten or fifteen hundred plants, or more, in a day.

In the fifth, or Holing-in Planting, which is sometimes used in the nursery, in light loose ground: also sometimes with potatoes, &c., in pliable soils; the ground being previously dug or trenched, and a line placed, it is thus performed: a person with a spade takes out a small spit of earth, to form a little aperture, in which another person directly deposits a plant, &c. The digger at the same time taking another spit at a little distance, turns the earth thereof into the first hole over the roots: placing directly another plant in the second opening, the digger covers it with the earth of a third spit, and so on to the end of the row.

In the sixth, or Drill Planting, which is by drawing drills with a hoe from two to four

or five inches deep, for the reception of seeds and roots, and is a convenient method for many sorts of large seeds, such as walnuts, chesnuts, and the like; sometimes also for broad beans, and always for kidney-beans, and peas; likewise for many sorts of bulbous roots, when deposited in beds by themselves; the drills for these should be drawn with a common hoe, two or three inches deep; and for large kinds of bulbous roots, four or five inches in depth, covering in the seeds and roots with the earth, always to the depth of the drills.

In the seventh, or Bedding-in Planting, which is frequently practised for the choicer kinds of flowering bulbs, such as Hyacinths, &c., also for the larger seeds of trees, as acorns, large nuts, and other larger kinds of seeds, stones, and kernels, it is performed by drawing the earth from off the tops of the beds some inches in depth, then planting the seeds or roots, and covering them over with the earth, drawn off for that purpose; for which the ground should be previously dug or trenched over, raked, and formed into beds three or four feet wide, with alleys between; then with a rake or spade trimming the earth evenly from off the top of the bed into the alleys, from two or three to four inches deep for bulbous roots, and for seeds, one or two, according to what they are, and their size; afterwards, for bulbous roots, drawing lines along the surface of the bed, nine inches distance, placing the roots bottom downward, along the lines, six or eight inches apart, thrusting the bottom into the earth: but when for seeds, they may be scattered promiscuously; and having thus planted one bed, then with the spade, let the earth that was drawn off into the alley be spread evenly upon the bed again over the roots or seed, &c., being careful that they are covered all equally the above depth, raking the surface smooth and fine.

This method is in occasional practice, in planting several kinds of the larger prime sorts of bulbous-rooted flowers in beds; and nursery-men also practise it in planting many of their larger seeds, nuts, &c.

And another method of this kind is occasionally practised in some parts, particularly for planting potatoes in low wet grounds, which is by dividing the ground into beds, four feet wide, with alleys two or three feet in width; then digging the beds, and placing the potatoe-sets in three rows along each bed, a foot asunder in the rows: this done, the alleys are dug one spade depth, casting the soil upon the beds over the sets, so as to cover them four or five inches deep: in this way, where the ground is very wet, the alleys drain the moisture from the beds, so

as sometimes to afford great crops. Sometimes, in low moist grounds, that are in grass or sward, the beds are marked out as above, and without digging the ground; placing the potatoe sets immediately upon the sward, then digging the alleys, first turning up the sward, and placing it topsy-turvy upon the bed, so as to be sward to sward over the sets; then finishing by applying more earth from the alleys, to cover in the sets, the proper depth of four or five inches. This, in some counties, is called the lazy-bed method, because the ground is not dug over.

In the eighth, or Furrow Planting, which is by drawing furrows with a plough, and depositing sets or plants in them, covering in also with the plough: it is sometimes practised for planting potatoe-sets in fields, and has been adopted in planting young trees for large tracts of forest-tree plantations, where the cheapest and most expeditious method is required; but this method can be practised only in a light pliable ground, and is performed thus: a furrow being drawn, one or two persons are employed in placing the sets or plants in the furrow, whilst the plough following immediately with another furrow, turns the earth in upon the roots of the plants. This is not a mode to be much advised.

In the ninth, or Dibble Planting, which is the most commodious method for most sorts of fibrous-rooted seedling plants, particularly all the herbaceous tribe; also for slips, off-sets, and cuttings both of the herbaceous and shrubby kinds; likewise for some kinds of seeds and roots, such as broad-beans, potatoe-sets, Jerusalem artichokes, and horse-radish-sets, with numerous sorts of bulbous roots, &c., it is expeditiously performed with a dibble or setting-stick, by making a narrow hole in the earth for each plant, inserting one in each hole always as the work proceeds.

Having a dibble or setting-stick, it is used by thrusting it into the earth in a perpendicular descent, in depth as the particular plants, &c., may require; directly inserting the plant, seed, or set, as each hole is made, closing it immediately by a stroke of the dibble. In setting any kind of plants, slips, cuttings, &c., having long shanks or stems, it is proper to make holes a proportionable depth, to admit them a considerable way in the ground: for example, cabbage-plants, savoys, &c., should be planted down to their leaves; slips and cuttings should be inserted two parts of three, at least, in the ground; being particularly careful in dibbling in all sorts of plants, to close the holes well in every part about the roots, by striking the dibble slantways into the ground, so as to strike

the mould first firmly up to the root and fibres, at the same time bringing it close to the stem. See **DIBBLE**.

In the tenth mode, or Trowel Planting, it is performed with a garden trowel, made hollow like a scoop, and is useful in transplanting many sorts of young fibrous-rooted plants with balls of earth about their roots, so as not to feel their removal.

The trowel is employed both in taking up the plants, and planting them.

In the eleventh, or Planting with Balls of Earth about the Roots, which is the removing a plant with a large ball of earth about its roots, so as by having its roots firmly attached to the surrounding earth, it still, during the operation, continues its growing state, without receiving any, or but very little check from its removal: this is often practised more particularly for the more delicate and choicer kinds of exotics, both trees, shrubs, and herbaceous plants; and occasionally for many of the fibrous-rooted, flowery plants, both annuals, perennials, and biennials, even in their advanced growth and flowering state, when particularly wanted to supply any deficient compartments; though it is not so eligible for bulbous-rooted kinds: likewise, when intended to remove any sort of tree or plant out of the proper planting season, as very late in spring, or in summer, it is proper to transplant it with a good ball of earth, to preserve it more certainly in a state of growth. Some trees and shrubs are more difficult to remove with a ball than most kinds of herbaceous fibrous-rooted plants, though many of the tree and shrub kinds having very fibry roots, also readily rise with good balls.

In transplanting any of the tree and shrub kinds by this method, if they grow in the full ground, the operator must be careful to begin to open a trench with a spade at some distance from and round the stem, perhaps a foot, or two or three, according to the size of the tree and expansion of the roots, digging a sort of trench all round, a spade or two wide, or more if large trees, and in depth below all the roots; all the time having great care not to disturb the ball or mass of earth between the stem and trench, but preserve it as entire as possible. When the whole has been detached, the plant should be removed into the situation for which it is intended, with the whole of its ball about its roots.

When trees or shrubs, with balls to their roots, are intended to be sent to considerable distances, they should be placed singly in osier baskets, in order to preserve the ball; having a basket for each tree; the baskets to be of an upright make, in width and depth in proportion

to the ball, with two handles at top, especially if large, and generally worked rather open at the sides, as sometimes the basket and all is placed in the ground, when the plant cannot be readily removed without danger of breaking the ball of earth about it.

In respect to the method of planting in pots in general, having the pots and mould ready for the reception of the plants, previous to planting them place some pieces of tile, potsherds, or oyster-shell, &c., over each hole at the bottom of the pots, to prevent the holes being clogged and stopped with the earth, and the earth from being washed out with occasional watering; also to prevent the roots of the plants getting out: then having secured the holes, put some earth in the bottom of each pot, from two or three to five or six inches or more in depth, according to the size of the pot, and that of the roots of the plant; then insert the plant in the middle of the pot upon the earth, in an upright position, making its roots, if without a ball of earth, spread equally every way; directly adding a quantity of fine mould about all the roots and fibres, shaking the pot to cause the earth to settle close thereto: at the same time, if the root stand too low, shake it gently up; and, having filled the pot with earth, press it gently all round with the hand, to settle it moderately firm in every part, and to steady the upright posture of the plant, raising the earth however within about half an inch, or less, of the top of the pot, as it will settle lower; for some void space at top is necessary to receive waterings occasionally: as soon as the plant is thus potted, give it directly a moderate watering to settle the earth more effectually close about all the roots, and promote their rooting more expeditiously in the new earth; repeating the waterings both before and after they have taken root, as occasion may require.

In transplanting plants in pots from one pot to another, they may in general be shifted with the whole ball of earth contained in the pot about their roots entire, so as to preserve the plant all along in its growing state, as scarcely to shrink or retard its growth by the operation; for plants growing singly in pots, and of some standing, whose roots and fibres have established themselves firmly in the earth, will readily remove out of the pots with the entire ball in one compact lump, surrounding all the roots and fibres, retaining their growing state by still drawing nourishment from the surrounding ball of earth.

The removing of plants from one pot to another with balls, is in some cases to be avoided; as where a plant appears diseased or in

a bad state of growth, as it is most probable the fault is in the root or earth; therefore, it is eligible to shake the whole entirely out of the earth, in order to examine its roots, and trim off all decayed and other bad parts; then, having a fresh pot, and some entire new compost, replant the tree, &c., therein.

In potting plants from the full ground, or beds of earth, &c., if they have been previously pricked out at certain distances, and have stood long enough to fix their roots firmly, many sorts may be potted with balls, particularly most of the herbaceous, fibrous-rooted kinds, and many of the shrubby tribe, by taking them up carefully with the garden-trowel, or with a spade, as may be convenient, according to the size of the plants; and, if necessary, pare the balls round to fit the pot.

Seedling plants, or those raised from seed-beds, by their growing so close together, rarely admit of potting with balls to their roots; so that when it is intended to pot such, they must be drawn out of the earth with the root as entire as possible, and be potted separately in small pots, shifting them occasionally into larger.

Sometimes in pot-planting, to save room, and for other purposes, several small plants are planted in each pot, especially when designed as nursery-pots, to receive either small seedlings, off-sets, slips, cuttings, &c., just to strike them, and forward them a little at first, either in hot-beds, or for removing them to different situations, such as occasional shade, shelter, &c., and in which some sorts of small slips and cuttings are sometimes planted many together, in one or more wide pots, especially where large supplies of some particular sorts are required, such as myrtle cuttings and pipings of pinks, &c., sometimes to the amount of a hundred or two of these small sets in one capacious pot or wide store pan. The small seedlings, slips, cuttings, off-sets, &c., when they are a little forwarded, or properly rooted, and shoot a little at top, should be all potted off, in proper time, each in a separate pot, especially if plants of any duration; giving them small pots at first, and as they increase in size shifting them into larger ones.

When any large growing plants, such as orange- and lemon-trees, or any other kinds, are become too large for pots, they should be shifted into tubs: these tubs should be made of full-inch thick staves, and adapted to the size of the respective plants; each tub to be well hooped with iron, and furnished with two hooked or bow iron handles at top, by which to move them, either by hand, or, when very large tubs, to receive poles between two men for moving

the plants where wanted; having holes at the bottom of the tubs to discharge the superfluous moisture; placing some stones, &c., to prevent the holes being clogged with the earth; the method of planting and transplanting being the same as in Pot-Planting.

In the twelfth mode, or Planting in Pots, which is practised to all tender exotics, in order for moving them to shelter occasionally, such as all kinds of green-house and hot-house plants; and likewise for many sorts of hardy flowering-plants, for the convenience of moving them occasionally to adorn particular compartments; and for the convenience of moving some curious sorts when in flower to occasional shelter from the sun's rays and excessive rains, in order to preserve their beauty and prolong the time of their bloom; such as the fine auriculas, carnations, &c.

In planting in this way, it is highly requisite carefully to adapt the sizes to the size and nature of the different plants intended to be potted: if small plants, begin first with small pots, one plant only to each pot, especially if to remain; but according as the different plants advance in growth shift them into pots one or two sizes larger, which may be requisite to many sorts once a year, to others once in two or three years, according to circumstances.

Garden-pots for this use are of several regular sizes, from two to sixty in a cast, distinguished at the pot-houses accordingly; as twos, sixes, twelves, sixteens, twenty-fours, thirty-twos, forty-eights, sixties, or sixty-fours, &c., each pot having one or more apertures at bottom to discharge the superfluous moisture. They are sold by the potters at so much per cast, large and small, all of a-price; those of only two in a cast the same as those of sixty; and from two shillings to half a crown or three shillings per cast is the general price. See POT, GARDEN.

Sometimes, instead of baskets, small young trees and other plants with balls, intended to be sent to any distance, are put separately in pots, and when they are to be placed in the full ground, each should be turned out of the pot with the ball entire.

Trees and other plants that have generally grown in pots, where they have been of some standing, have the whole earth by means of the numerous fibres formed into one compact lump, so that it will readily come out entire and firm; or to such as do not so easily quit the pot, a long blade of a knife, or some other thin instrument, may be thrust down between the outside of the ball and pot all round, and it will then readily come out, either in drawing by the stem of the plant, or by striking the edge of the

VOL. II.

pot with something; or, if small plants, you may turn the pot mouth downward, and strike the edge gently against any firm substance. In replanting those potted plants, if the sides of the ball of earth is much matted with the fibres of the root, it is proper to pare off the grossest part, together with a little of the old earth, especially if to be planted in pots again; then put it in a pot a size larger than before, filling up all round with fresh mould, finishing with a moderate watering.

In regard to the proper state and preparation of trees for planting, it may be observed that young trees, both of the fruit and forest kinds, are the most suitable, and succeed best; as from three or four to six or eight feet in height, and from three or four to five or six years old. See FOREST-, DWARF-, and STANDARD-TREES.

In forest-trees, the straightest, most vigorous, and thriving plants of the respective kinds should always be chosen.

In preparing for planting, in taking up the trees out of the nursery, the greatest care is necessary in raising them with as great a spread of roots as possible, which is often ill attended to, especially when large orders of plants are to be drawn in a hurry. The ground about the trees should always be opened with the spade widely round the roots, and deep enough to get to their bottom without hacking and cutting them with the spade, but so as to raise each plant with all its roots as entire as possible. After having taken up the trees out of the nursery, &c., it is also of great moment to have them replanted as soon as possible in the places allotted for them; for, although by properly covering the roots with litter, or, if sent to any considerable distance, by tying them in bundles, and packing them up with plenty of straw about the roots, and afterwards closely matted round, they may be preserved in tolerable good condition a fortnight or longer—yet, where it is possible to plant them the same day, or in a day or two after, before the small fibres are shrunk or dried, it will be of much advantage in the first growth of the trees; but when this cannot be done they should be immediately laid in the ground in a trench.

In preparing for planting, the roots must have an occasional trimming, not however to retrench or reduce any but the maimed and decayed parts; therefore previous to planting examine the root, and cut out all such parts as have been broken or damaged in taking up, and any casual decayed parts or other blemishes, being careful to leave all the sound roots every where entire; leaving also all the small fibres that are fresh and vigorous, only trimming off

such as are become dry and mouldy; suffering all the main roots to remain, mostly at full length, except just to tip off their ends a little on the under side, sloping outward; and reduce any very long stragglers, and shorten long perpendicular tap-roots, more particularly of fruit-trees, to prevent their running down into a bad soil, and to promote their throwing out others horizontally.

And with regard to the preparation of the heads of the trees, the principal care is to trim off the straggling shoots and branches from the stems, leaving the heads for the generality entire, only just retrenching very irregular branches, and shortening any very long stragglers; always suffering the main or leading top shoot to remain at length, particularly in forest-trees, and all others that are to grow to a lofty stature.

Fruit-trees, however, sometimes require a more accurate regulation of the head preparatory to planting, particularly dwarfs for espaliers and walls. If the fruit-tree is taken from the nursery at one year old from the budding and grafting, and with its first shoot from budding and grafting entire, this first shoot must necessarily be shortened or headed down to force out lateral wood below, to furnish the bottom properly; but this heading down is not necessary at the time of planting, but should remain till spring, until the tree has taken fresh root and begins to shoot; for the head remaining greatly promotes the rooting; when in March or the beginning of April, head it down within half a foot, or five or six eyes of the insertion of the bud or graft, and the shoot so headed will throw out, from its remaining lower eyes, several lateral branches the ensuing summer.

If it is two, three, or more years old from the budding and grafting, and the first shoots were headed down in the nursery at the proper time, it is proper to plant it with its whole head entire, only retrenching any irregular branch, or any very luxuriant shoot; or thin out the worst of such as are evidently too close or crowded, leaving however all the regular branches at full length, except just to reduce any very long ramblers.

For new planting trees it is very improper to retrench the branches too severely, and cut all that remains short, as is very often practised, on a supposition of strengthening their roots, which however has often the contrary effect; for the branches and leaves imbibe the refreshing influence of the air, &c., which, being conveyed to the roots, proves nutrimental, and contributes exceedingly towards vegetation, and consequently promotes the rooting afresh more expeditiously and effectually. Besides, by a se-

vere retrenching and a general shortening, of fruit-trees in particular, in most sorts the very parts where fruit would have been soon first produced are cut off, and it will probably cost the tree two or three years growth to furnish new branches equal to those cut away, as well as retard its bearing in proportion. And it often happens by such a general amputation of the branches of all new planted trees at the time of planting, that they, for want of branches to collect vegetative nourishment, either make very little progress in shooting for two or three years after, or sometimes, when they do shoot, throw out a profusion of unnecessary wood from the remaining eyes or buds.

Therefore if young fruit-trees at planting, whether dwarfs or standards, are furnished with five or six or more good regular principal branches, of one, two, or more years growth, it is improper to retrench any part of them, and disfigure the tree, particularly apples, pears, plums, and cherries, which should at all times be but sparingly shortened; and since several good branches being already obtained in the proper parts to give the head its first regular form, they in their turn readily furnish more; and if there is a vacancy in any part, it will be better to endeavour to fill it by stopping some of the young shoots produced the summer after planting, by either pinching or pruning them in May or June the same year to three or four eyes, or cutting them down to that length in the winter or spring following.—Some fruit-trees, however, such as peaches, nectarines, &c., against walls, require most of their young shoots to be shortened annually.

Forest-trees, &c., in their preparation previous to planting, after being drawn out of the nursery, should only have the blemished roots trimmed, and all branches from the lower part of the stem pruned off, cutting the lower ones close, the others to two, three, or four inches, particularly the deciduous kinds, leaving the head always tolerably branchy, and mostly entire; not to trim away all the branches to one leading shoot only, as is often practised, but leave a proportionable share of the upper more erect branches, to form some tolerable head, and only just retrenching the lower stragglers, very long rambling luxuriant, and very irregular growths, to preserve a little regularity; being particularly careful to leave always the top or leading shoot perfectly entire, unless it is decayed, or is very crooked, bending much downwards, &c., in which cases, if any straight shoot is conveniently situated, the crooked part may be retrenched down to the straight shoot, which leave entire to run up in height, as with-

out a leader a tree can never aspire to any considerable stature; for the leader, by its annual erect shoot, gradually increases the length of the stem, and, as it advances, sends out a supply of laterals to furnish the head, branching and spreading.

In planting tall trees, where it is designed to form shade, shelter, or blind as soon as possible, very little reduction of the branches of the head should be suffered, only to reduce any very irregular growers.

In removing pretty large trees of any sort with considerable heads, especially when very spreading or crowded, it may be proper to reduce the whole regularly in some proportion to the root, that the winds may not have too much power to incommode it after planting; in which cases it may be necessary to retrench or reduce some of the most extensive lower branches, and thin out some where much crowded, reducing others down to some convenient lateral branch they may support, so as each reduced branch may, notwithstanding its reduction, terminate in a leader, having its top entire, not to exhibit naked ends of branches, standing up like stumps.

In respect to the preparation for planting of all the shrub kind, only just trim the straggling under branches and shoots from the lower part of the stem, retrenching any luxuriant of the heads that seem to shoot away very irregularly and vigorously at the expense of the neighbouring branches, and reducing long rambles, &c., just to preserve a little regularity.

All new planted tall trees should be staked as soon as planted, in order to support them steady every where till they are well rooted and have somewhat established their roots, that winds may not overset, or otherwise incommode them; particularly all trees of six, eight, or ten feet high, and upwards; one tall stout stake being placed to each tree, or more, if the trees are of large size, sharpening the lower ends, and driving them firmly into the ground near the stem; or if larger trees, place it slantways, at a little distance, so as its top reach the upper part of the stem, on the opposite side to that most exposed to the winds, in which it will have the greatest effect; but large trees with full heads, should generally have very tall strong stakes, three to each tree, placed triangular-ways, in an oblique or slanting direction, afterwards binding the stems of the trees firmly to the stakes, previously wrapping some soft substance, such as hay-bands, &c., round them, at the part where it is to be fastened to the stakes, in order to save the bark from being rubbed off against the stakes by the motion of the winds, which is more par-

ticularly necessary to tall plants that are much exposed.

Large trees of considerable stature, with full heads, are often supported with ropes suspended from the top of the stem three different ways, straining them tight, and the end of each rope staked securely down to the ground; so that whatsoever way the wind blows the ropes stay the tree still in its upright position.

Such new planted trees as are exposed to cattle should each be well fortified all round the stem with thorn bushes.

The general season of planting, for all sorts of trees, is autumn and spring, as from the beginning of the decay of the leaf, in October, until December, for the former; though evergreens may be begun to be transplanted towards the middle or latter end of September and continued till December. And for the spring planting, February and March is the principal time, but may be continued occasionally until April; and several sorts of tender young evergreens succeed best when planted the beginning of that month, or later. Much, however, in this business, must depend on the soil and state of the weather.

In preparing to plant herbaceous fibrous-rooted plants, care is to be had to remove them with good roots; young seedlings, &c., especially require particular care in drawing them with proper roots. When they are to be taken all clean up, they may be readily loosened and raised out of the earth with some instrument with all their fibres entire; but when they are only to be thinned, they do not admit of this, as it would disturb the remaining plants, so must be drawn out by hand carefully, with as much root as possible.

Many sorts of fibrous-rooted plants, however, are so hardy, and apt to grow, that if taken up almost any how, with a little root, they will strike: it is nevertheless advisable to use care in drawing all sorts for planting with tolerable roots, as they will in proportion make more progress in their future growth. And as to any trimming preparatory to planting, very little is wanted, only in some sorts, just shortening very long naked spindly roots, and trimming any straggling fibres; though in numbers of plants of this tribe hardly any trimming at all is required, either in root or top.

PLATANUS, a genus containing plants of the exotic deciduous tree kind.

It belongs to the class and order *Monoecia Polyandria*, and ranks in the natural order of *Amentaceæ*.

The characters are: that the male flowers are compound, forming a globular ament. The

calyx is a few small jags. The corolla scarcely apparent: the stamina have oblong filaments, thicker at top, coloured: anthers four-cornered, growing round the filament at the lower part—female flowers forming a globe, numerous, on the same tree: the calyx has many very small scales: the corolla has many petals, concave, oblong, club-shaped: the pistillum many awl-shaped germs, ending in awl-shaped styles; with a recurved stigma: there is no pericarpium: fruits many, collected into a globe: the seed roundish, placed on a bristle-shaped peduncle, and terminated by the awl-shaped style; with a capillary pappus adhering to the base of the seed.

The species are: 1. *P. orientalis*, Oriental Plane Tree; 2. *P. occidentalis*, American Plane Tree.

The first has the stem tall, erect, and covered with a smooth bark, which annually falls off; it sends out many side branches, which are generally a little crooked at their joints; the bark of the young branches is of a dark brown, inclining to a purple colour; the leaves are placed alternate, on foot-stalks an inch and a half long; the leaves themselves are seven inches long and eight broad, deeply cut into five segments, and the two outer are slightly cut again into two more; these segments have many acute indentures on their borders, and have each a strong midrib, with many lateral veins running to the sides; the upper side of the leaves is of a deep green, and the under side pale. The flowers come out upon long peduncles hanging downward, each sustaining five or six round balls of flowers; the upper, which are the largest, are more than four inches in circumference; these sit very close to the peduncle. The flowers are so small as scarcely to be distinguished without glasses; they come out a little before the leaves, which is in the beginning of June; and in warm summers the seeds will ripen late in autumn, and if left upon the trees will remain till spring, when the balls fall to pieces, and the bristly down which surrounds the seeds helps to transport them to a great distance with the wind. It is a native of Asia.

There are two varieties, as the Maple-leaved, which has not its leaves so deeply cut as those of the eastern plane: they are divided into five segments, pretty deep, but are not lobed, like those of the occidental plane. The petioles are much longer than in either of the species, and the upper surface of the leaves is rougher, so that they might be taken for different sorts, if it was not known that they rose from the same seeds.

The Spanish Plane, which has larger leaves

than either of the sorts, and are more divided than those of the occidental, but not so much as those of the oriental. Some of the leaves are cut into five, and others into three lobes only; these are sharply indented on the edges, and are of a light green; the footstalks are short, and covered with a short down. This is by some called the Middle Plane Tree, from the leaves being of a shape between the two species.

These are highly ornamental trees for pleasure-grounds.

The second species grows to a large size, the stem very straight, and of equal girth most part of the length; the bark is smooth, and annually falls off like that of the former; the branches extend wide on every side; the young ones have a brownish bark, but the old ones a gray bark; the footstalks of the leaves are three inches long; the leaves are seven inches long, and ten broad; they are cut into three lobes or angles, and have several acute indentures on their borders, with three longitudinal midribs, and many strong lateral veins. The leaves are of a light green on their upper side and paler on their under. The flowers grow in round balls like the former, but are smaller. The leaves and flowers come out at the same time with the former, and the seeds ripen in autumn. It is a native of most parts of America.

This is also an ornamental tree in the same situations.

Culture.—These plants may be increased by seed, layers, and cuttings; but principally in the two last methods.

The best season for sowing the seeds is autumn, if they can be procured, otherwise in the spring; upon a somewhat lightish, mellow soil: the ground having been dug and raked, it should be formed into four-feet wide beds, and the seeds then scattered evenly on the surface, and raked in, or with the back of a rake the earth be previously trimmed off the surface near half an inch deep into the alleys; then sowing the seed, and directly, with the rake turned the proper way, drawing the earth evenly over the seeds, and trimming the surface smooth, when many of the plants will rise in spring, but probably not generally till the spring following. When they are one or two years old, they should be planted out in nursery-rows, two feet asunder, and about half that distance in the lines; to remain till of a proper size for being finally set out.

In the layer method, some stout plants must be planted for stools, which in a year after must be headed down near the bottom, that they may throw out many shoots near the ground convenient for laying; which, in the autumn after

they are produced, should be laid down by slit-laying; and by the autumn after, they will be well rooted, and form plants two or three feet high, which may be separated, and planted in nursery-rows, as the seedlings. They succeed very readily in this way.

Most of the sorts take tolerably by cuttings of the strong young shoots; but the latter more freely than the former kinds. The most proper season for planting them is the autumn, as soon as the leaf falls, or occasionally in the spring; choosing a moist soil for the purpose, when many of the cuttings will grow, and make tolerable plants by the autumn following.

These last two methods are the only ones in order to continue the distinct varieties effectually.

They have a very ornamental effect in all sorts of plantations, from their large growth and the great size of their leaves.

PLEASURE-GROUND, any ornamented ground round a residence. It comprehends all the ornamental compartments or divisions of ground and plantation; such as lawns, plantations of trees and shrubs, flower compartments, walks, pieces of water, &c., whether situated wholly within the space generally considered as pleasure-ground, or extended over ha-ha's, or by other communications, to the adjacent fields, parks, paddocks, or out-grounds.

In designs for pleasure-grounds, modern improvements reject all formal works, such as long straight walks, regular intersections, square grass plots, corresponding parterres, quadrangular and angular spaces, inclosed with high clipped hedges, &c., as well as all other uniformities; instead of which, open spaces of grass ground of varied forms and dimensions, and winding walks, all bounded with plantations of trees, shrubs, and flowers, in various clumps and other distributions, are exhibited in a variety of imitative rural forms, as curves, projections, openings, and closings, in imitation of a natural assemblage, having all the various plantations open to the walks and lawns. A spacious open lawn of grass ground being generally first exhibited immediately in the front of the mansion, or main habitation, sometimes widely extended in open space on both sides to admit of greater prospect, &c., and sometimes more contracted towards the habitation, widening gradually outward, and having each side embellished with plantations of shrubbery, groves, thickets, &c., in clumps, and other parts, in sweeps, curves, and projections, towards the lawn, &c., with breaks or openings of grass spaces at intervals, between the plantations; and serpentine gravel-walks winding under the shade of the trees: extended plantations

being also carried round next the outer boundary of the ground, in various openings and closings, having also gravel-walks winding through them, for shady and private walking; and in the interior divisions of the ground serpentine winding walks exhibited, and elegant grass opens, arranging various ways, all bordered with shrub-beries, and other tree and shrub plantations, flower compartments, &c., disposed in a variety of different rural forms and dimensions, in easy bendings, concaves, projections, and straight ranges, occasionally; with intervening breaks or openings of grass ground, between the compartments of plantations, &c., both to promote rural diversity, and for communication and prospect to the different divisions; all the plantations being so variously arranged, as gradually to discover new scenes, each furnishing fresh variety, both in the form of the design in different parts, as well as in the disposition of the various trees, shrubs, and flowers, and other ornaments and diversities.

So that in these designs, according to modern gardening, a tract of ground of any extent may have the prospect varied and diversified exceedingly, in a beautiful representation of art and nature, so that in passing from one compartment to another, new varieties present themselves in the most agreeable manner; and even if the figure of the ground be irregular, and its surface has many inequalities, in risings and fallings, and other irregularities, the whole may be improved without any great trouble of squaring and levelling, as, by humouring the natural form, even the very irregularities may be made to conceal their natural deformities, and carry along with them an air of diversity and novelty. In these rural works, however, we should not entirely abolish all appearance of art and uniformity; for these, when properly applied, give an additional beauty and peculiar grace to all natural productions, and sets nature in the fairest and most advantageous point of view. One principal point in laying out a pleasure-ground, is for the designer to take particular care that the whole extent of his ground be not taken in at one view, as where the contrary is the case there is a tameness and want of proper effect produced.

It is impossible to give any directions for planning a pleasure-ground; as the plan may be varied exceedingly, according to the natural figure, position, and situation of the land, and taste of the designer.

In respect to the situation, it must be immediately contiguous to the main house, whether high or low situated: however, a somewhat elevated situation, or the side or summit of some moderate rising ground, is always the most

eligible on which to erect the chief habitation, arranging the pleasure-ground accordingly; such an exposure being the most desirable, both for the beauty of the prospect and healthfulness of the air; a low level situation neither affording a due prospect of the ground, or the adjacent country, besides being liable to unwholesome dampness, and sometimes inundation in winter: there are, however, many level situations, forming plains or flats, that possess great advantages both of soil and prospect, and the beauties of water without too much moisture; there are also sometimes large tracts of ground, consisting both of low and high situations, as level plains, hollows, eminences, declivities, and other inequalities, which may be so improved as to make a most desirable pleasure-ground, as the scene may be varied in the most beautiful manner imaginable; but as the choice of situation and scope of ground is not always attainable, every one must regulate his plan in the most commodious manner possible, agreeable to the nature of the particular situation, extent of ground, and plan which has been adopted.

The extent of pleasure-grounds may be various, according to that of the estate or premises, and other circumstances, as from a quarter or half an acre to thirty or forty or more.

The ground for this purpose should previously be well fenced in, by a wall, paling, hedge, or parts of each sort, and in some parts a fosse or ha-ha, where it may be necessary to extend the prospect, either at the termination of a lawn, walk, or avenue; and the close fences should generally be concealed withinside, particularly the wall and paling fences, by a range of close plantation, unless where the wall may be wanted for the culture of wall-fruit. But sometimes, when the pleasure-ground adjoins to a fine park, paddock, or other agreeable prospect, the boundary fence on that side is often either a low hedge, or a ha-ha; but many prefer the latter, especially at the termination of any spacious open, both to extend the prospect more effectually, and give the ground an air of greater extent than it really has, at a distance; the ha-ha being sunk, nothing like a fence appears, so that the adjacent park, fields, &c., appear to be connected with the grounds.

The arrangement of the several divisions, both internal and external, must be wholly regulated by the nature and extent of the ground.

And in whatever mode such grounds are laid out, the whole of the different quarters, walks, and other parts, should be kept in an exact and neat order.

PLIANT MEALY TREE. See **VIBURNUM**.

PLINIA, a genus comprising a plant of the exotic shrubby kind for the stove.

It belongs to the class and order *Icosandria Monogynia*, and ranks in the natural order of *Rosaceæ*.

The characters are: that the calyx is a one-leaved perianth, five- or four-parted: segments acute, flat, small: the corolla five- or four-petalled: petals ovate, concave: the stamens have numerous capillary filaments, the length of the corolla: anthers small: the pistillum is a superior, small germ: style awl-shaped, longer than the stamens: stigma simple: the pericarpium is a very large drupe, globular, grooved: the seed single, very large, globular, smooth.

The species is *P. pedunculata*, Red-fruited *Plinia*, or *Myrtle*.

It has the leaves opposite, petioled, simple, even, like those of myrtle, ovate: the flowers are peduncled, the length of the leaves, subumbelled: the calycine leaflets four, ovate, concave, spreading, coloured, reflex: the petals, four or eight, obovate, sessile, twice as long as the calyx: the filaments very many, capillary, the length of the petals, inserted into the receptacle: anthers roundish: germ inferior, roundish angular: the style filiform, the length of the stamens: the stigma simple: the berry roundish, the size of a plum, with eight swellings, one-celled, umbilicated, with a four-toothed calyx, red and sapid: seed single, sub-globular. It is a native of Brasil, flowering in January and February.

Culture.—It is increased by the seeds, which should be procured from abroad, and which should be sown in pots, filled with rich mould, plunging them in a bark hot-bed, when they appear in the same season. They may also be increased by planting cuttings of the young shoots, in the later spring and summer months, in pots filled with good earth, covering them with hand- or bell-glasses, and watering them occasionally. They may be so rooted as to be fit for removing into separate pots the same year.

It is highly ornamental in stove-collections, from its flowering in the winter season.

PLUM. See **PRUNUS**.

PLUM, MAIDEN. See **CAMOCCLADIA**.

PLUMBAGO, a genus containing plants of the herbaceous flowering perennial kinds.

It belong to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Plumbagines*.

The characters are: that the calyx is a one-leaved perianth, ovate-oblong, tubular, five-cornered, rugged, with a five-toothed mouth, permanent: the corolla one-petalled, funnel-form: tube cylindrical, narrower at top, longer

than the calyx: border five-cleft, from erect-spreading, with ovate segments: nectary of five very small acuminate valves in the bottom of the corolla, inclosing the germ: the stamina have five, awl-shaped filaments, free within the tube of the corolla, placed on the valves of the nectary: anthers small, oblong, versatile: the pistillum is an ovate germ, very small: style simple, the length of the tube: stigma five-cleft, slender: the pericarpium is an oblong capsule, five-cornered, terminated by the permanent style, one-celled, five-valved, clothed with the calyx: the seed single, oblong, fastened to a thread, pendulous.

The species cultivated are: 1. *P. europæa*, European Leadwort; 2. *P. zeylanica*, Ceylon Leadwort; 3. *P. rosea*, Rose-coloured Leadwort; 4. *P. scandens*, Climbing Leadwort.

The first has a perennial root, striking deep into the ground: the stalks many, slender, three feet and a half high, and channelled: the leaves three inches long and two broad, smooth, entire, of a grayish colour. The upper part of the stalks send out many slender side branches, which have small leaves on them: these and also the principal stalks are terminated by tufts of either blue or white flowers, which are small and succeeded by rough hairy seeds. It is a native of the South of Europe and Africa, flowering here in October.

The second species is a perennial plant, with a strong fibrous root, from which arise many slender stalks, growing near four feet high: the leaves about three inches long, and an inch and half broad near their base, ending in acute points; they are alternate, and on short foot-stalks: the upper part of the stalks divides into small branches, having smaller leaves on them, and terminating in spikes of flowers: seeds covered with the prickly calyx: the upper part of the stalks and the calyx of the flowers are very glutinous, sticking to the fingers, and entangling small flies that settle on them. It is a native of the East Indies and of the Society Isles, flowering from April to September.

The third is a shrubby plant, which frequently grows to the height of four or five feet, and is perpetually putting forth flowering spikes; these continue a long time, and hence, with proper management, may be kept in flower during most part of the year. The calyx has capitate glutinous hairs scattered over it: the filaments are dilated at the base and arched: the capsule superior, clothed with the permanent calyx, ovate-oblong, ending in the subulate-setaceous style, obscurely five-cornered: the seed oblong, acuminate above, of a dark blood-red or ferruginous colour, suspended by a filiform umbilical

chord, springing from the base of the capsule. It is a native of the East Indies.

The fourth species has a suffrutescent stem, scandent, sometimes decumbent, loose, flexuose, branched, round, striated, smooth: the leaves are alternate, ovate-lanceolate, acuminate, nerved, spreading, entire, smooth on both sides: two smaller leaflets at the base of the middle, and two above it: the petioles very short, compressed, channelled, half embracing, membranaceous at the edge, with a red spot at the base underneath: the flowers terminating, subpanicked, commonly in spikes, sessile, scattered, approximating: the leaflets sessile under the flowers; the calyx inferior, bellying in the middle and towards the base, five-grooved, with glanduliferous hairs: the border of the corolla five-parted: parts roundish, emarginate, with a very short point in the middle: the nectarice roundish, yellow, round the germ, inserted into the bottom of the calyx: the filaments thickened, approximating, awl-shaped: anthers placed on the top of the filaments, blue: style the length of the stamens: seed coated, as it were included in a capsule, and covered with the permanent calyx. It is a native of South America and Jamaica, flowering in July and August.

Culture.—The first sort is increased by parting the roots in the autumn, when the stems decay, and planting them in a dry soil. They should afterwards be kept clean from weeds, and have proper support.

The three other sorts should be raised from seeds, which should be sown in pots, in the spring, and plunged in hot-beds. They likewise may sometimes be raised by planting slips and cuttings in pots, and plunging them in the same sorts of hot-beds.

These are all ornamental flowering plants; the first in the pleasure-grounds, and the others in pots among hot-house collections.

PLUMERIA, a genus containing plants of the succulent flowering exotic kind, for the stove.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Contortæ*.

The characters are: that the calyx is a five-parted perianth, blunt, very small: the corolla one-petalled, funnel-form: tube long, widening gradually: border five-parted, from erect-spreading; segments ovate-oblong, oblique: the stamina have five, awl-shaped filaments, from the middle of the tube: anthers converging: the pistillum is an oblong, bifid germ: styles scarcely any: stigma double, acuminate: the pericarpium consists of two foliicles, long, acuminate, ventricose, bent downwards, nodding, one-celled, one-valved: the seeds numerous;

oblong, inserted into a larger ovate membrane at the base, imbricate.

The species are: 1. *P. rubra*, Red Plumeria, or Jasmine; 2. *P. alba*, White Plumeria; 3. *P. obtusa*, Blunt-leaved Plumeria; 4. *P. pudica*, Close-flowered Plumeria.

The first rises to the height of eighteen or twenty feet: the stalks are covered with a dark green bark, having marks where the leaves are fallen off; they are succulent, abound with a milky juice, and within are somewhat woody: towards the top they put out a few thick succulent branches, with leaves at their ends of a light-green colour, full of milky juice, having a large midrib and many transverse veins: at the ends of the branches also come out the flowers in clusters; shaped like those of the Oleander or Rose bay, of a pale-red colour, and having an agreeable odour. They are produced in this climate in July and August.

The second species has the habit of the first, but is not much branched, and rarely exceeds fifteen feet in height; it abounds, like that, in a milky juice: the flowers are in spikes, white with a yellowish eye, and diffuse a very sweet odour to a considerable distance. It is a native of Campeachy.

The third produces small white flowers resembling those of the second: the leaves are oval-lanceolate, and the peduncles branched. Some describe it as a thick tree, exceeding the middle size, with an ash-coloured, smooth, milky bark, a juicy brittle wood, and spreading, thick, twisted branches: the leaves quite entire, large, flat, smooth, scattered, with many transverse ribs: the flowers terminating, in compound spreading upright racemes. It is a native of the West Indies.

The fourth species is an upright milky shrub, five feet in height, of the same habit with the others: the leaves oblong, flat, veined: the flowers numerous, yellowish, the border continuing erect and shut, even after they drop; being rolled up like the flowers of Hibiscus: they succeed each other continually for two months together; and have an odour much more agreeable than that of the preceding species, or even of any other known flower. It is a native of South America.

Culture.—These plants are capable of being increased by seeds and cuttings of the young branches.

The seeds should be procured from the native situation of the plants, and be sown in pots, filled with a light sandy compost, plunging them in a hot-bed, covered by glasses, or the bark-bed in the stove, when they readily vegetate; and when the plants have attained a few

inches in growth, they should be removed into separate pots, of a small size, which must be plunged in beds of the same kind as the above.

The cuttings should be made from the young branches, and after being laid in the stove or some other dry situation, to dispel their succulence, and heal over the wounds, be planted out during the summer months, in pots, filled with light dry mould, plunging them in the bark-bed of the stove, giving occasional shade and very slight waterings, till they have stricken fresh root, and when they have become well rooted, they may be removed into separate pots, being managed as other stove exotics.

They afford much ornament and variety among collections of stove plants; especially the red sort; and when set out with other potted plants in the summer, have a delightful fragrance.

POISON-ASH. See RHUS.

POISON-NUT. See STRYCHNOS.

POISON-OAK. See RHUS.

POLEMONIUM, a genus containing plants of the fibrous-rooted, herbaceous flowering perennial kind.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Campanaceæ*.

The characters are: that the calyx is a one-leaved perianth, half-five-cleft, inferior, goblet-shaped, acute, permanent: the corolla one-petalled, wheel-shaped: tube shorter than the calyx, closed by five valves placed at the top: border five-parted, wide, flat: segments roundish, blunt: the stamina have five filaments, inserted into the valves of the tube, filiform, shorter than the corolla, inclining: anthers roundish, incumbent: the pistillum is an ovate, acute, superior germ: style filiform, the length of the corolla: stigma trifid, revolute: the pericarpium is a three-cornered capsule, ovate, three-celled, three-valved, opening three ways at top, covered: partitions contrary to the valves: the seeds very many, irregular, sharpish.

The species are: 1. *P. coeruleum*, Common Polemonium; 2. *P. reptans*, Creeping Polemonium, or Greek Valerian.

The first has a perennial, fibrous root: the herb smooth: the stems upright, rising to the height of eighteen or twenty inches, seldom more, leafy, panicled: the leaves alternate, unequally pinnate, many-paired; leaflets elliptic-lanceolate, quite entire: the corolla between bell-shaped and wheel-shaped, blue: the calyx bell-shaped, half-five-cleft: the filaments dilated at the base and membranaceous: capsule clothed with the calyx, ovate-globular, absolutely three-grooved, thin, subpellucid: seeds

six in each cell, in a double row, fastened to the inner angle of the cell, variously angular, eroded on the surface, of a dark rust colour. It is a native of Asia, flowering in May.

There are varieties with white flowers, with variegated flowers, and with variegated leaves.

The second species has creeping roots, by which it multiplies very fast. The leaves have seldom more than three or four pairs of leaflets, which stand at a much greater distance from each other than those of the common sort, and are of a darker green. The stalks rise nine or ten inches high, sending out branches their whole length. The flowers are produced in loose bunches, on pretty long peduncles; they are smaller than those of the common sort, and of a lighter blue colour. It is a native of America.

Culture.—These plants may be increased by seeds and parting the roots.

The seeds should be sown in the spring, upon a bed of light earth, and when the plants are pretty strong they should be pricked out into another bed of the same earth, four or five inches asunder, shading and watering them until they have taken new root; keeping them clear from weeds until the beginning of the autumn, and then transplanting them into the borders of the pleasure-ground. The plants are not of long duration; but by taking them up in autumn and parting their roots they may be continued some years: but the seedling plants flower stronger than those from offsets.

The varieties can only be continued by parting the roots at the above season. They should have a fresh light soil, which is not too rich, as the roots will be apt to rot in winter, and the stripes on the leaves to go off.

The second sort may be increased by seeds or offsets in the same manner, and is equally hardy, but much less beautiful.

They afford ornament among flowery plants in the borders and other parts.

POLEY-MOUNTAIN. See **TEUCRIUM**.

POLYANTHES, a genus containing plants of the bulbo-tuberous rooted herbaceous flowering perennial exotic kind.

It belongs to the class and order *Hexandria Monogynia*, and ranks in the natural order of *Coronariæ*.

The characters are: that there is no calyx: the corolla one-petalled, funnel-form: tube curved inwards, oblong: border patulous, with six ovate segments: the stamina have six filaments, thick, blunt, at the jaws of the corolla: anthers linear, longer than the filaments: the pistillum is a roundish germ, at the bottom of the corolla: style filiform, mostly shorter than the corolla: stigma trifid, thickish, melliferous:

VOL. II.

the pericarpium is a roundish capsule, obtusely three-cornered, at the base involved in the corolla, three-celled, three-valved: the seeds very many, flat, incumbent, in a double row, semi-orbiculate.

The species is *P. tuberosa*, Tuberoze, or Indian Tuberous Hyacinth.

It has an oblong bulb-like tuberous root, which is white, sending forth a few long but very narrow leaves, and an upright, firm, straight stem, of considerable length, which is terminated by a long spike of large white flowers, placed in an alternate manner. It is a native of India.

There are varieties with a double flower, with striped leaves, and with a smaller flower. The last is frequent in the south of France, whence the roots have been often brought here early in the spring, before those roots have arrived from Italy which are annually imported; the stalks of it are weaker, and do not rise so high, and the flowers are smaller than those of the common sort, but in other respects it is the same.

The Genoese are the people who cultivate this plant to furnish all the other countries where the roots cannot be propagated without great trouble and care, and thence the roots are annually sent to this and other countries. In most parts of Italy, Sicily, and Spain, the roots thrive and propagate without care where they are once planted.

It has been long cultivated in this country for the exceeding beauty and fragrancy of its flowers.

Culture.—These plants are chiefly increased by off-sets from the roots.

The blowing roots that are annually brought from abroad, for sale, are mostly furnished with off-sets, which should be separated previously to planting; those also raised here in the garden are frequently furnished with off-sets, fit for separation in autumn, when the leaves decay. They should be preserved in sand during winter, in a dry sheltered place; and in the beginning of the spring, as March, be planted out either in a bed of light dry earth in the full ground, or, to forward them as much as possible, in a moderate hot-bed, sheltering them in cold weather either by a frame and lights or with mats on arched hoops, letting them enjoy the full air in mild weather, giving also plenty of water in dry seasons during the time of their growth in spring and summer.

They should remain in this situation till their leaves decay, in autumn; then they should be taken up, cleaned from earth, and laid in a box of dry sand, to preserve them till spring following, at which time such roots as are

2 K

large enough to blow may be planted and managed as directed below, and the smaller roots planted again in a nursery-bed, to have another year's growth; afterwards planting them out for flowering.

The roots of these plants are mostly sold at the rate of about twelve or fifteen shillings per hundred, care being taken always to procure as large roots as possible, as on this depends the success of having a complete blow.

In order to blow them in a perfect manner, they require artificial heat in this climate, and should be planted in pots, and plunged in a hot-bed, under a deep frame, furnished with glass lights; or placed in a hot-house, where they may be blowed to the greatest perfection, with the least trouble.

The principal season for planting them is as above; but in order to continue a long succession of the bloom it is proper to make two or three different plantings, at the interval of about a month.

Where dung hot-beds are employed, six inches depth of earth, or old tan, should be laid, in which to plunge the pots; but if bark or tan be used, no earth is necessary, as the pots may be plunged immediately into the bark. Having the hot-beds ready, and the roots provided, and some proper sized pots, twenty-fours, one for each root, fill the pots with light rich earth; and, after having divested the roots of all loose outer skins, and all off-sets, plant one in each pot, in depth, so as the top of the root be about an inch below the surface of the earth, plunging all the pots in the hot-bed close together, or so that the bed may contain the number required; and as soon as they are all thus placed, put on the lights of the frame.

In the hot-house method, the pots of roots as above should be plunged to their rims in the bark-bed, or placed in the front part of the house; but the former is the better method.

They afterwards require to have a portion of fresh air daily admitted, by tilting the upper ends of the lights, keeping them close down on nights; also moderate waterings, which however should be applied very sparingly, till the roots begin to shoot, when repeat them moderately as occasion may require, taking care when the shoot begins to advance to admit fresh air more freely, in proportion, to strengthen the stems, according as they advance in height; and when they have risen near the glasses, it is proper to deepen the frame, either by the addition of another at top, or by raising it at bottom six or eight inches, in order to give the stems sufficient room to shoot to their full stature, repeating this once or twice, as the

growth of the plants renders it necessary, still assisting them with plenty of water, and a large portion of fresh air daily, either by raising one end of the lights as above; or when the plants are advanced some tolerable height, and in the warm season, the lights may be taken away entirely, occasionally, in fine mild days, which will strengthen and inure them gradually to the full air: but always draw on the lights again towards the evening, or at the approach of a sharp air, cold blasts, or heavy rains; but as the summer approaches begin to expose them fully, only giving occasional shelter in cold nights or very wet weather, either by the glasses, or mats supported on hoop arches, till they begin to flower, which will be about the middle or latter end of June, or beginning of July; when the plants in their pots may be removed where wanted; either to adorn any of the garden compartments, or any apartment of the house, a tall straight stake being placed to each plant, to fasten the stem to for support.

The plants must still be duly supplied with water all the time of their bloom, as every other day, or oftener, in very hot dry weather.

Sometimes roots when planted in May in the full ground, will shoot tolerably strong, and produce flowers in autumn.

They are all highly ornamental, but especially the single and double sorts, among other tender potted plants. The dwarf and variegated sorts also afford a fine variety.

POLYANTHUS. See PRIMULA.

POLYANTHUS-NARCISSUS. See NARCISSUS.

POLYGALA, a genus containing plants of the woody, under shrubby, and herbaceous perennial kinds.

It belongs to the class and order *Diadelphia Octandria*, and ranks in the natural order of *Lomentaceæ*.

The characters are: that the calyx is a five-leaved, small perianth: leaflets ovate, acute: two below the corolla, one above that, and two in the middle, subovate, flat, very large, coloured, (the wings) permanent: the corolla sub-papilionaceous: standard almost cylindrical, tubular, short, with a small reflex mouth, bifid: wings; keel concave, compressed, ventricose towards the tip: appendix of the keel, in most of the species two three-parted pencil-shaped bodies, fastened to the keel towards the tip: the stamina have diadelphous filaments (eight connected) inclosed within the keel: anthers eight, simple: the pistillum is an oblong germ: style simple, erect: stigma terminating, thickish, bifid: the pericarpium is an obcordate capsule, compressed with an acute margin, two-

celled, two-valved: partition contrary to the valves; opening at each margin: the seeds solitary, ovate (with a glandular umbilicus).

The species cultivated are: 1. *P. myrtifolia*, Myrtle-leaved Milk-wort; 2. *P. Chamæbuxus*, Box-leaved Milk-wort.

The first has a shrubby stem, covered with a smooth brown bark, rising four or five feet high, and sending out several spreading branches towards the top: the leaves about an inch long and a quarter of an inch broad, lucid green, and sessile. The flowers are produced at the ends of the branches; they are large, white on the outside, but of a bright purple within: wings expanded wide, and standard incurved. It continues flowering most part of the summer: each cell of the seed-vessel contains one hard smooth shining seed. It grows naturally at the Cape of Good Hope.

The second species rises with a slender, branching, woody stalk, about a foot high, when it grows upon good ground, but on a rocky soil it is seldom more than half that height. The branches are closely garnished with stiff smooth leaves, of a lucid green: from between the leaves, towards the top of the branches, the flowers come out upon very short peduncles; they are white on the outside, but within are of a purplish colour mixed with yellow, and have a grateful odour. According to Martyn, it is an elegant little evergreen shrub, of low growth, with leaves like those of Box, producing flowers from May to October, but most plentifully in May and June: each flower stands on a peduncle, proceeding from a kind of triphyllous cup, formed of floral leaves. It is a native of Austria, &c.

Culture.—The first sort may be increased by seeds, which should be sown in small pots, filled with light loamy earth; soon after they are ripe, placing them where they may have the morning sun only till October, when they should be placed under a hot-bed frame, and be plunged into old tanners bark which has lost its heat, where they may be defended from frost during the winter, and in the spring the pots should be plunged into a moderate hot-bed, which will bring up the plants. When these appear, they should not be too tenderly treated, but have a large share of free air admitted to them; when they are fit to transplant, they should be carefully shaken out of the pots, and separated, planting each into a small pot filled with soft loamy earth, and plunged into a very moderate hot-bed, to forward their taking new root, shading them from the sun, and gently refreshing them with water as they may require. When they are rooted, they must be gradually inured to the open air, and in June they may be

placed abroad in a sheltered situation, where they may remain till the middle or latter end of October, according as the season proves favourable; then they must be removed into the green-house; and treated in the same way as the Orange-tree, being careful not to give them too much wet during the winter season.

The second sort was formerly thought difficult to raise by seeds; but at present it is readily increased by parting its creeping roots, and planting them in bog earth, on a shady border, where it thrives very well, and spawns much.

The first affords variety when set out among other potted plants of the green-house kind; and the latter, in the borders, &c.

POLYGONUM, a genus containing a plant of the herbaceous annual kind.

It belongs to the class and order *Octandria Trigynia*, and ranks in the natural order of *Holoraceæ*.

The characters are: that the calyx is a turbinate perianth, coloured internally, five-parted; segments ovate, blunt, permanent: there is no corolla, unless the calyx be taken for it: the stamina have commonly eight filaments, awl-shaped, very short: anthers roundish, incumbent: the pistillum is a three-sided germ: styles commonly three, filiform, very short: stigmas simple: there is no pericarpium: calyx involving the seed: the seed single, three-sided, acute.

The species cultivated is *P. orientale*, Oriental Persicaria.

It has a root composed of many strong fibres, growing in tufts: the stem is jointed, eight or ten feet high, the lower part becomes woody, and as thick as an ordinary walking-cane, of a fine green, and a little hairy: the leaves are alternate, often a foot long, and six inches broad in the middle, terminating in acute points; they have one strong midrib, and several transverse veins, which run upwards towards the point; their surfaces are a little hairy, the upper of a bright green, and the under paler: the petioles are broad, half embracing at their base: the flowers in close terminating spikes, seven or eight inches long, hanging downwards: the stamens five, six or seven. The stipules are deserving of notice, being unusual in their form, and making the stem look as if ruffled. Thunberg remarks that the margin of the stipules is entire and revolute. It is a native of the East Indies, flowering from July to October.

There is a dwarf variety, and another with white flowers.

Culture.—This plant is constantly raised from seeds, and is said to rise from scattered seeds better than when sown: but where they are sown, it should be in autumn, soon after they

are ripe, as when sown in the spring they rarely succeed; or if some plants come up, they seldom grow so strong. They may be removed in the spring into the borders of the plantation or flower-garden, giving them room. They are, however, commonly sown in the spring with other annuals; thinning the seedlings, when they appear, so as to stand a foot apart. About the beginning of July the side shoots should be pruned off, to make them advance in height, and preserve them within compass; and when they are pruned up to five or six feet, they may be permitted to shoot out side branches. It delights in a rich moist soil. The plants are sometimes sown on hot-beds, in March, in order to be more forward.

These plants are distinguished for their superior stature and the brilliancy of their flowers: they frequently grow to the height of eight or ten feet, and rival the sun-flower.

POPPY, PRICKLY. See ARGEMONE.

POPULUS, a genus containing plants of the hardy deciduous tree kind.

It belongs to the class and order *Diœcia Octandria*, and ranks in the natural order of *Amentaceæ*.

The characters are: that in the male—the calyx is an oblong ament, loosely imbricate, cylindrical, composed of one-flowered, oblong, flat scales, torn at the edge: the corolla has no petals: the nectary one-leafed, turbinate below, tubular, ending at top obliquely in an ovate border: the stamina have eight, extremely short filaments: anthers four-cornered, large: female—the calyx and scales as in the male: the corolla has no petals: nectary as in the male: the pistillum is an ovate-acuminate germ: style scarcely manifest: stigma four-cleft: the pericarpium is an ovate capsule, two-celled, two-valved: valves reflex: the seeds numerous, ovate, flying with a capillary pappus.

The species cultivated are: 1. *P. alba*, White Poplar; 2. *P. tremula*, Trembling Poplar Tree, or Asp; 3. *P. nigra*, Black Poplar Tree; 4. *P. dilatata*, Lombardy or Po Poplar Tree; 5. *P. balsamifera*, Common Tacamahaca Poplar Tree; 6. *P. canadensis*, Heart-leaved Tacamahaca Poplar Tree; 7. *P. laevigata*, Smooth Poplar Tree; 8. *P. monilifera*, Canadian Poplar Tree; 9. *P. Græca*, Athenian Poplar Tree; 10. *P. heterophylla*, Various-leaved Poplar Tree; 11. *P. angulata*, Carolina Poplar Tree.

The first grows very tall, with a straight

trunk, covered with a smooth whitish bark: the leaves are smooth, blackish green above, but having a thick white cotton underneath; they are about three inches long, on petioles an inch in length, flatted and grooved on each side: in young trees the leaves are roundish, but in adult ones angular, divided into three, five or seven lobes; they are without glands, either at the base or on the serratures. The flowers are exactly similar to those of the second sort. It is a native of Europe, from Sweden to Italy; also of Siberia and Barbary.

There are two varieties; the Common White Poplar, and the Great White Poplar, or Abele. In the first, the leaves are rounder, and not much above half the size of those of the latter; and the shoots of the latter are paler, the catkins are larger, and the down of the seeds whiter and longer.

In the latter the leaves are large, and divided into three, four, or five lobes, which are indented on their edges; they are of a very dark colour on their upper side, and very white and downy on their under, standing upon foot-stalks, which are about an inch long: the young branches have a purple bark, and are covered with a white down, but the bark of the stem and older branches is gray. In the beginning of April the male flowers or catkins appear, which are cylindrical, scaly, and three inches long, and about a week after come out the female flowers on catkins, which have no stamina like those of the male. Soon after these come out, the male catkins fall off, and in five or six weeks after, the female flowers will have ripe seeds inclosed in a hairy covering, when the catkins will drop, and the seeds be wafted by the winds to a great distance. According to Mortimer, the best sort comes from Holland and Flanders. Hence in some places it is called Dutch Beech.

The second species has a green smooth bark. The leaves at first breaking out are hairy above and cottony underneath, but when full grown are smooth; they are slightly heart-shaped, smaller and more approaching to circular than in the preceding, with a few angular teeth on the edges. According to Linnæus they are rolled inwards at the edge, and have two glands running one into the other on the inner side above the base. He also observes, that the leaf-stalks are flatted towards the end, whence the perpetual trembling of the leaves with every breath of wind: but the petioles being flat in the White and Black Poplars, as well as in this, Dr. Stokes accounts better for the phenomenon, from the plane of the long leaf-stalks being at right angles to that of the leaves, which allows them a

much freer motion than could have taken place had their planes been parallel. This trembling of the leaves has been so generally noticed as to have become proverbial. This tree is of speedy growth, and will grow in any situation or soil, but worst in clay. It impoverishes the land: its leaves destroy the grass, and the numerous shoots of the roots spread so near the surface, that they will not permit any thing else to grow. The wood is extremely light, white, smooth, woolly, soft, durable in the air. Pannels or pack-saddles, canns, milk-pails, clogs, pattens, &c., are made of the wood. It is a native of Europe, from Sweden to Italy.

The third has a naked lofty trunk, covered with an ash-coloured bark, and a regular handsome head: the leaves are slightly notched on their edges, smooth on both sides, and of a light green colour. They have no glands at the base, but the serratures are glandular on the inner side: the petioles are yellowish. It is a tree of quick growth, and on the banks of rivers and in moist situations it grows up to a great height, throwing out numberless suckers from the roots. It loves a moist black soil, and bears cropping well: the bark, being light like cork, serves to support the nets of fishermen. The wood is not apt to splinter: it is light and soft, and sometimes used by turners. It is incomparable, according to Evelyn, for all sorts of white wooden vessels, as trays, bowls, and other turner's ware; and is of especial use for the bellows-maker, because it is almost of the nature of cork, and for ship-pumps, though not very solid, yet very close and light. It affords useful rafters, poles, and rails, and in a proper soil makes a very quick return for such purposes. It is excellent for flooring-boards, and is much used for the purposes of deal in some midland counties. It is a native of Europe, from Sweden to Italy.

The fourth species differs from the third sort chiefly in its close conical manner of growth, like the Cypress. The leaves are greater in breadth than length, whereas in that the longitudinal diameter is the greatest.

This has been esteemed by some as no more than a variety of that; and indeed it can scarcely be considered as a distinct species. It has been stated in Mr. Young's Annals, that the Italian Poplar is fit to cut for building uses in twelve years, and that at eight years growth they are forty feet high. For rafters, small beams, studs, boards, &c. it is very durable.

The peculiar use of it in this country has hitherto been for ornamental plantations, and covering unsightly buildings. To the latter purpose its upright close conical mode of growing, with its feathering very readily down to the very

ground, particularly adapts it. The conic form of it, as a deciduous tree, is peculiar. Among evergreens we find the same character in the Cypress; and both trees in many situations have a good effect. One beauty the Italian Poplar possesses which is almost peculiar to it; and that is the waving line it forms when agitated by wind. Most trees in this circumstance are partially agitated; one side is at rest, while the other is in motion; but the Italian Poplar waves in one simple sweep from the top to the bottom, like an ostrich-feather on a lady's head. All the branches coincide in the motion; and the least blast makes an impression upon it, when other trees are at rest. Although this tree sometimes has a good effect, when standing single, it generally has a better when two or three are planted in a clump.

In the fifth, the growth seems not to be to a very large size: the bark is smooth, like that of the third sort; the young branches have much the same appearance, but their annual shoots are seldom more than a foot in length. The leaves resemble those of the Pear-tree; are about four inches long, and an inch and half broad in the middle, drawing towards a point at each end; their upper side is of a deep green, and their under side is hoary; they stand upon long foot-stalks, and are placed without order upon the branches. The male flowers come out from the side of the branches in long catkins, in April and May, and fall off soon after; their stamens are numerous, irregular in height, and crowned with headed anthers of a purple colour. The hermaphrodite flowers are produced at the end of the shoots upon long slender peduncles, in very loose catkins, having a leafy involucre under each, which is oval and entire; and from the bosom of that arises the peduncle, which is very short. Upon the top is placed the petal or calyx, (or nectary, according to Linnæus) shaped like a wide cup, having a large style in the centre, and two stamens on one side, terminated by pyramidal purple anthers. These flowers appear in July, and are succeeded by oval capsules terminating in a point, and inclosing downy seeds. The scaly covers of the buds abound with a tenacious balsam in the spring, becoming liquid by heat. It is of a yellowish colour and a fragrant scent. It is a native of Canada and some other parts of North America.

There are varieties, with much wider leaves; the Daurian, with a longer ovate leaf, more like this sort; and an Altaic variety, with a lanceolate leaf.

In Siberia the trunk is straightish, not tall, covered with an ash-coloured bark; the wood reddish, closer, and a little harder than in the

common Poplars. The branchlets in the Altaic tree are more slender, and rod-like; in the Daurian thick, short, knobbed, and wrinkled, with a yellow skin sometimes of a very deep colour: the leaves in the rod-like variety ovate-acuminate, in the Altaic commonly lanceolate; in the common Daurian ovate and thicker, so as to be in a manner coriaceous; in both very sharp, serrate, quite smooth, shining as if varnished, deep green above, pale underneath: aments terminating, thick, the female ones ripening in June; containing ovate thick rugged capsules, subcalyced with the receptacle, scarcely peduncled.

The sixth species is resinous, like the preceding; but the leaves are different, being hollowed next the petiole and drawn out at the point. It flowers earlier, as in March. It is a native of Canada.

The seventh is a native of North America, flowering in March and April.

The eighth species is a native of Canada, flowering in May.

The ninth resembles the tenth species in growth and foliage. It is a native of the islands of the Archipelago, flowering in March and April.

The tenth species is a large tree, having numerous branches, veined and angular; the leaves broad and slightly serrate: flowers in loose aments, making little show. It is a native of Virginia and New York, flowering in April and May.

The eleventh shoots very strong, and is generally cornered, covered with a light green bark like some sorts of willow. The leaves upon young trees, and also upon the lower shoots, are very large; but those upon older trees are smaller: as the trees advance their bark becomes of a lighter colour, approaching to gray: the aments are like those of the third sort; and the anthers are purple. It grows naturally in Carolina, where it becomes a very large tree, and flowers in March.

Culture.—All the sorts are readily increased by cuttings, layers, and suckers.

The planting of the cuttings is the most expeditious mode of raising all these trees, as they grow freely without any trouble, when made either from the young year-old shoots, a foot and a half in length, and planted a foot in depth, or large truncheons of two, three, or more years growth, from about a yard to five or six feet long, planted in moist places: though these large cuttings or truncheons are not proper for general plantations, only in some particular parts, as in a marshy or watery situation, where shade and shelter, &c., may be required as soon

as possible, in which they may be planted finally to remain, putting them in to the depth of one or two feet.

In order to raise plants for regular plantations, or for handsome standards, it is the best method to raise them principally from young cuttings of one year's growth, or two at most. These young cuttings should be made about fifteen or eighteen inches long, and planted out in nursery-rows two feet asunder, placing each cutting two parts or half-way in the ground, and about a foot distant in the lines, they readily take root, and make good shoots the following summer, care being taken to trim off the straggling laterals in order to encourage the leading shoot to grow straight, and rise more expeditiously in height: after having had from two to four or five years growth in this situation, they may be finally removed for the purposes for which they are wanted.

The layers may be laid down in autumn, choosing the lower young shoots, which are conveniently situated, laying them by slit-laying. They will be well rooted, and fit to remove by the autumn following, in nursery-rows, to have two or three years growth.

The suckers, which some of the sorts send up in abundance from the roots, as the fifth sort, may be taken up after the fall of the leaf, and be planted in nursery-rows, as directed for the cuttings. They form good plants in two years.

The plants raised in any of the above methods, after having obtained from two or three to five or six years growth, are of a proper size for furnishing plantations, or other places.

These trees are also capable of being raised from seed, if care be taken to gather a quantity as soon as ripe; and sow them in autumn, in beds either broad-cast or in drills, half an inch in depth.

These trees may be employed in assemblage for ornament in out-grounds, which are detached from fine lawns and walks, as on account of the great litter the falling of their catkins in some sorts occasions, they are improper, but are excellent for planting towards the boundaries of parks, paddocks, and fields, the sides of rivers and brooks, and to intersperse with other trees in large plantations, in any interior parts. The White Poplar, the Carolina, Tacamahaca, Lombardy and Athenian Poplars, are proper to introduce as ornamental trees, and are finely adapted to be employed in assemblage in forming large avenues, open groves, and clumps in parks, &c., though any of the sorts are eligible on the same occasions to increase the variety; and all the sorts may be employed

to advantage in any large tracts of plantation. To marshy grounds no trees are better adapted than Poplars, especially the first three species, all of which thrive remarkably in moist situations.

As forest or timber trees, the White, Black, Tremulous, and Lombardy Poplars are proper to be employed.

Marshy lands may be improved to much advantage by coppices of these trees, to cut every four, five, or six years for poles, and other small purposes; being planted in rows a yard asunder, and in seven years they will be fit to cut for many small uses, and the stools shooting up again strong, afford a cutting every four or five years afterwards.

Some sorts may also be planted occasionally to form hedges in moist or other situations, more particularly the Lombardy Poplar, as this sort is peculiar in branching out numerously from the bottom upwards, and may be planted hedge-fashion along the sides, or top of outward watery ditches, in large plants, so as at once to form a hedge; they being topped to five, six, or seven feet.

PORRUM. See **ALLIUM**.

PORTLANDIA, a genus containing plants of the trailing evergreen exotic kinds, for the stove.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Rubiaceæ*.

The characters are: that the calyx is a five-leaved perianth, superior: leaflets oblong-lanceolate, permanent: the corolla one-petalled: tube long, funnel-form-ventricose: border shorter than the tube, five-parted, acute: the stamina have five awl-shaped filaments, declined, almost the length of the corolla, from the bottom of the tube: anthers linear, erect, the length of the corolla: the pistillum is a five-cornered germ, roundish, inferior: style simple, the length of the stamens: stigma oblong, obtuse: the pericarpium is an obovate capsule, five-streaked, five-cornered, retuse, two-celled, two-valved; opening at the top; partition contrary: seeds very many, roundish, compressed, imbricate.

The species cultivated is *P. grandiflora*, Great-flowered Portlandia.

It has a shrubby, upright stem, branched, knotty, with a smooth bark cracking longitudinally: the branches opposite, spreading, round, scarcely divided, leafy, covered with smooth green bark: the buds are gummy: the leaves opposite, spreading, somewhat lengthened at the point, equal at the base, entire, very smooth, paler beneath, marked with alternate veins projecting on both sides: the footstalks

are very short, thick, round below but flattish above: the stipules between the leaves, connate, triangular, pointed, very smooth, pale, closely pressed to the branch: the flowers axillary, mostly solitary, between the stipules, peduncled, a little nodding, very large, white, beautiful, most fragrant at night, in the bud yellowish tipped with red. It was found in the West Indies, flowering in July and August.

Culture.—These plants may be raised either from seeds or cuttings.

The seeds when procured should be sown in pots, filled with light earth, in the spring, plunging them in the tan-bed, in the stove. When the plants are sufficiently strong, they should be removed into separate pots, and be replunged in the bark hot-bed, where they must be constantly kept.

The cuttings of the young shoots should be planted out singly, in pots filled with the same sort of mould, plunging them in the bark-bed of the stove; when they have taken good root they should be removed into larger pots, replunging them into the tan-bed, where they must remain.

They afford a fine effect, when trained on the back part of the stove, in their larger flowers.

PORTULACA, a genus containing plants of the herbaceous and shrubby kinds.

It belongs to the class and order *Dodecandria Monogynia*, and ranks in the natural order of *Succulentæ*.

The characters are: that the calyx is a bifid perianth, small, compressed at the tip, permanent (two-leaved, superior, caducous): the corolla has five petals, flat, erect, blunt, larger than the calyx: the stamina have many filaments (to twenty), capillary, shorter by half than the corolla: anthers simple: the pistillum is a roundish germ (half inferior): style simple, short: stigmas five, oblong, the length of the style: the pericarpium is a covered capsule, ovate, one-celled (cut transversely): receptacle free (five, free, separate): the seeds numerous, small.

The species cultivated are: 1. *P. oleracea*, Garden Purslane; 2. *P. Anacampseros*, Round-leaved Purslane.

The first is an annual herbaceous plant, with a round, smooth, procumbent, succulent stem, frequently red, and diffused branches, often throwing out fibres at the joints: the leaves more or less wedge-shaped, oblong, blunt, fleshy, smooth, quite entire, sessile, clustered, especially at the ends of the branches: the flowers are sessile, scattered: corollas yellow, spreading; petals subtruncate at the tip and emarginate: the stamens ten: the capsule one-

celled, opening horizontally: the seeds round, black, very small. It is a native of both Indies, China, Cochinchina, and Japan. It was formerly much in request as a wholesome salad and pickle, but at present is little in use.

There are several varieties. The garden Purslane differs from the wild, only in having larger and more succulent leaves. If it be permitted to scatter the seeds, in two years it will become in every respect like the wild plant. Of the two other varieties, one is with deep-green leaves, and the other with yellow leaves, which is called Golden Purslane.

The second species has a shrubby stalk, four or five inches high: the leaves are thick and succulent. At the top of the stalk comes forth a slender peduncle about two inches long, supporting four or five red flowers, appearing in July, but not succeeded by seeds in England. It is a native of the Cape of Good Hope.

Culture.—These plants may be increased by seeds and cuttings, according to the different kinds.

In the first sort, the seeds should be sown in slight drills, or broad-cast over the surface, at different times, in the spring and summer, from March to June, or later, at the distance of three weeks, the early sowing being made on slight hot-beds, but the late ones in the open borders, where the ground is light and dry, occasional light waterings being given afterwards, both before and after the plants appear, which must remain where they come up, and are mostly fit for cutting in the course of a month or five weeks. In gathering them, the young tops should be cut off with a knife, and they afterwards shoot out fresh tops.

In the second sort the cuttings should be planted in pots filled with light dry mould, and plunged in the tan-bed, in order to promote their rooting, moderate shade and waterings being given till they have stricken good root, being kept in the stove, and afterwards managed as the succulent kinds of aloes.

The last affords variety among other stove potted plants.

PORTULACARIA, a genus furnishing a shrubby plant of the succulent green-house kind.

It belongs to the class and order *Pentandria Trigynia*.

The characters are: that the calyx is a two-leaved perianth, coloured, permanent: leaflets roundish, concave, obtuse, spreading very much, opposite: the corolla has five obovate petals, obtuse, quite entire, concave at top, flat at the base with the sides mutually incumbent, spreading very much, almost three times as long as the calyx, permanent: the stamina have five

awl-shaped filaments, very short, erect, two on each side of the germ, the other solitary: anthers erect, ovate: the pistillum is a three-cornered germ, superior, the length of the petals: style none: stigmas three, spreading very much, ascending at the tip, mucicated above: there is no pericarpium: the calyx and corolla, now erect, closely embrace the base of the seed: the seeds single, ovate-oblong, obtuse, winged-three-sided.

The species is *P. Afra*, African Purslane Tree.

It rises with a strong thick succulent stalk to the height of three feet, sending out branches on every side, so as to form a kind of pyramid; the lower branches being extended to a great length, and the others diminishing gradually to the top; they are of a red or purplish colour and very succulent. The leaves are also succulent and roundish, very like those of Purslane, whence the gardeners call it the Purslane Tree. It is a native of Africa. It is not known that it has yet flowered in this climate.

Culture.—It is readily increased by cuttings of the stems or branches, planted during any of the summer months, having been laid to dry for some days before, in pots filled with sandy earth, being placed in a frame, and shaded in hot weather, and protected from wet. They are also much forwarded by being plunged in the bark-bed of the stove. It must be placed in a warm glass case in winter, where it may enjoy the full sun, and should have very little water during that season. In summer the plants should be placed abroad in a sheltered situation, and in warm weather be refreshed with water twice a week; but the stalks being very succulent, too much wet is always hurtful.

These afford variety among other green-house plants.

POTATOES. See *SOLANUM*.

POTATOES, CANADA. See *HELIANTHUS TUBEROSUS*.

POTENTILLA, a genus containing plants of the herbaceous and shrubby kinds.

It belongs to the class and order *Icosandria Polygynia*, and ranks in the natural order of *Senticosæ*.

The characters are: that the calyx is a one-leaved, flattish, ten-cleft perianth: the alternate segments smaller reflex: the corolla has five roundish petals, spreading, inserted by their claws into the calyx: the stamina have twenty filaments, awl-shaped, shorter than the corolla, inserted into the calyx: anthers elongate-lunulate: the pistillum has numerous germs, very small, collected into a head: styles filiform, the length of the stamens, inserted into the side of

the germ : stigmas obtuse : there is no pericarpium : common receptacle of the seeds roundish, juiceless, very small, permanent, covered with seeds, inclosed within the calyx : the seeds numerous, acuminate-wrinkled.

The species chiefly cultivated are : 1. *P. fruticosa*, Shrubby Cinquefoil ; 2. *P. fragarioides*, Strawberry-leaved Cinquefoil ; 3. *P. recta*, Upright Cinquefoil ; 4. *P. Monspeliensis*, Montpellier Cinquefoil ; 5. *P. grandiflora*, Great-flowered Cinquefoil.

Other species may be cultivated for variety.

In the first, the whole plant is set with fine silvery hairs : the stems erect, clothed with a brown bark which cracks longitudinally, branching very much, about three feet (or in gardens four feet) high, frequently reddish : the leaves alternate, covering the branches, petioled, quinate-pinnate, or consisting of five rarely seven oblong leaflets, somewhat rolled back, quite entire, hairy underneath ; the upper ones ternate. Dr. Withering remarks, however, that the leaves can hardly be called pinnate, consisting of two pairs set cross-wise, rising from the same point, with a terminating one divided down to the base into three open segments ; and that the leaflets are linear-lanceolate, turned back at the edges, dark green above, pale underneath. Flowers terminating, solitary, peduncled, of a bright yellow or golden colour, and very ornamental. It is a native of Oeland, England, Siberia, and China, flowering here in June and July.

It has a beautiful appearance, in its numerous flowers.

The second species has the root somewhat tuberous : the leaves silky on hairy petioles, with three, five, or seven leaflets, which are ovate, opposite, serrate, lessening as they approach the base : the runners are decumbent. It is a native of Siberia.

The third has a stem about a foot high, rigid, covered with a pile rather than hairs, reddish, at top corymbed, or dividing into several peduncles forming a sort of umbel : the leaves are large, having each five or seven oblong villose leaflets, frequently of a russet colour, with ten or twelve blunt teeth ; when old almost naked : the lower ones are petioled, the upper ones sessile, finally becoming linear and stipular. The flowers are abundant on the top of the stem, erect on solitary peduncles, altogether making the stem panicled. It is a native of Germany and the South of Europe, flowering in June and July.

The fourth species is a perennial plant : the stalks grow erect, about a foot high ; they are very hairy : the leaflets oblong, serrate : the peduncles come out above the joints of the stalk :

the flowers are white and large : they come out in June ; and the seeds ripen in autumn. It is a native of the South of France.

The fifth has also a perennial root : the stems trailing : the leaflets ovate, obtuse, bluntly indented on their edges : the flowers larger than in the fourth sort, and the whole plant of a deeper green. It flowers in July, and the seeds ripen in autumn. It is a native of Switzerland and Siberia.

Culture.—The first sort may be readily increased by suckers, layers, and cuttings, which may be laid down or planted out in the autumn or spring season, and be removed into the nursery in the spring following ; and after having two or three years growth in that situation, they will be fit for planting out in the clumps and shrubby borders.

When removed from their natural situations into these places, the best season is in the autumn, before the frosts begin, that they may get well rooted. They should be watered occasionally in dry weather.

They succeed best in a cool moist soil and shady situation.

All the other kinds may be increased by parting the roots, and planting them out in the autumn, or by sowing the seeds either in the autumn or spring seasons.

They all afford ornament and variety in the different parts of pleasure-grounds.

POTERIUM, a genus containing plants of the herbaceous and shrubby perennial kinds.

It belongs to the class and order *Monoecia Polyandria*, and ranks in the natural order of *Miscellanæ*.

The characters are : that the calyx is a four-leaved perianth : leaflets ovate, coloured, caducous : the corolla four-parted : segments ovate, concave, spreading, permanent : the stamina have very many filaments, (thirty to fifty) capillary, very long, flaccid : anthers roundish, twin.—Female flowers in the same spike above the males : the calyx a perianth as in the male : the corolla one-petalled, wheel-shaped : tube short, roundish, converging at the mouth : border five-parted : segments ovate, flat, reflex, permanent : the pistillum has two, ovate-oblong germs, within the tube of the corolla : styles two, capillary, coloured, flaccid, the length of the corolla : stigmas pencil-form, coloured : the pericarpium is a berry formed of the tube of the corolla, hardened, thickened, closed : the seeds two : inverted.

The species are : 1. *P. Sanguisorba*, Lesser Upland or Common Garden Burnet ; 2. *P. hybridum*, Sweet Burnet ; 3. *P. spinosum*, Prickly Shrubby Burnet.

The first has a perennial root, penetrating deep into the earth: the stems nearly upright, from nine inches to a foot high, and a foot and half in cultivation; branched, striated, reddish, smooth except at bottom, where they are slightly hairy: the leaves unequally pinnate, on pretty long peduncles, next the root collected into a tuft, on the stem alternate: the leaflets smooth, pale or bluish underneath, deeply serrate about the edge, the lower ones on the same leaf commonly alternate, and the upper ones opposite: the bottom leaves have seven or eight pairs of roundish leaflets; the stem-leaves have five or six, or at top only two pairs of ovate pointed leaflets: the petiole is three-cornered, channelled, hairy, and somewhat membranaceous at the base. Stipules toothed: the flowers are peduncled in little roundish heads; greenish, sometimes purplish on the outside, the terminating one largest; each head has male flowers below, and female or fertile flowers above, expanding before the former, which are frequently imperfect hermaphrodites. It is a native of England, Germany, Switzerland, &c., flowering in May, and sometimes in April.

It is frequently cultivated for winter and spring salads, and for cool tankards.

The leaves and seeds are mildly astringent, and have been used in dysenteries and hæmorrhages.

The second species is a biennial plant, decaying soon after the seeds are ripe: the leaves are composed of three or four pairs of oblong leaflets, placed a little alternate; they are deeply indented, and have an agreeable scent: the stems two feet high, with one of these leaves at each joint, gradually diminishing in size to the top; and just above the leaf arises a long peduncle, which supports two or three small ones, each sustaining a small roundish spike of flowers. These appear in July, and are succeeded by seeds which ripen in autumn. It is a native of the South of France, Italy, and Barbary.

The third has a shrubby stalk, rising about three feet high, and dividing into several slender branches, armed with sharp branching thorns; the leaves are very small, unequally pinnate, with six or seven pairs of opposite leaflets, of a lucid green, and continuing all the year: the flowers of an herbaceous colour, in small heads at the ends of the branches: they appear the beginning of June, and there is a succession of them most part of the summer; but those only which come early, are sometimes succeeded by seeds in England. It is a native of the Levant.

Culture.—The first sort may be readily increased by seeds and parting the roots.

The seeds should be sown in the autumn, on

a bed or border of light mould, when they are perfectly ripened. When the plants have attained two or three inches in height, they should be planted out on a bed, at the distance of a foot, when for salads, or in the borders where they are to remain.

The roots may likewise be parted in the autumn, and planted where they are to remain, in the same manner as the above.

The second sort may be increased in the same way.

And the last sort may be raised from slips or cuttings, which should be planted in a bed of light earth during the summer season, and covered with glasses or in pots, and placed under a frame and glasses, giving shade and water occasionally.

They may also be had more forward by plunging the pots in a moderate hot-bed under glasses. They should be removed into separate pots when they have stricken good root and are well established. They should afterwards be protected from frosts in the winter, by being placed in a mild hot-bed, and have but little water in the winter season.

The first sorts are ornamental in the borders, clumps, and other parts, and the last among other potted greenhouse plants.

POT, GARDEN, such as are made use of for plants and flowers.

Pots of these kinds are particularly necessary in the culture of numerous sorts of plants, such as all tender exotics of the greenhouse and stove sorts, which must be planted in them for the convenience of moving them in and out of their departments as there may be occasion.

They are also exceedingly useful in raising many young seedlings and cuttings that require moving to occasional shade, shelter, and artificial heat; likewise for many young plants that are tender whilst young, and require to be removed under shelter for the first two or three winters, but become hardy enough afterwards to bear the full air the year round; and likewise to plant many of the more curious hardy flowering plants and others, and choice flowering shrubs, &c. in, to remove occasionally to adorn particular compartments or situations.

In general there are about eight different sizes of this sort of pots made use of, which are necessary in order to suit the different sorts of plants, as well as all sorts in their different stages of growth; as when the plants are young and of small size, they may be first planted in small ones, and as they increase in bulk be shifted into those a size larger, repeating it as often as necessary. See **PLANTING in POTS and SHIFTING PLANTS.**

The several sizes are in regular gradation, each size having its name for the convenience of readily supplying the sizes wanted for particular uses, being always reckoned by the cast at the houses, from two to sixty pots to each, according to their sizes, the largest having only two to a cast, and the smallest sixty; so that, being of eight different sizes or casts, they are distinguished by the following terms, twos, eights, twelves, sixteens, twenty-fours, thirty-twos, forty-eights, and sixties; the several casts from the twos being in a gradual diminution in size, and the price of the different casts is the same; those of two, &c., being as much as those of sixty, and so of the rest: from two to three shillings is the general price per cast at the potteries in the vicinity of London.

In garden pots there is also a particular shallow sort of a wide, squat, pan-form make, used on some occasions, especially among the myrtle-gardeners in the neighbourhood of London, in raising great quantities of these plants annually, in order to have always a regular succession advanced to proper growth, for the markets. These kinds of wide shallow pan-pots are employed to prick or plant out the requisite supplies of numerous small myrtle cuttings, in summer, &c., for annual propagation, and which are commonly called store-pans.

In these store-pans they generally prick a great number of such small slips or cuttings, at only about an inch or two apart, often to the amount of hundreds in each, just to strike them, and remain two or three months or more, till advanced a little in growth; in which time the pans thus stored are convenient for removing to different situations required, such as, at first planting or afterwards, either into a hot-bed, whereby to strike the cuttings more expeditiously, or for the same advantage, when in want of hot-beds, to be placed under a garden-frame and lights, or under hand-glasses, either with or without a hot-bed; and also for removing to a green-house or garden-frame, for protection in winter, &c., all of which being thus continued in them, according to the progress of growth which they make; so that, when they discover themselves to be well struck in bottom radicles and have shot a little top, they may be pricked out separately into small pots, or occasionally three, four, or five in larger ones, for a year, then separated as above, or sometimes bedded out in the spring in beds of natural earth, six or eight inches apart, to acquire an advanced state of growth till autumn, and then potted off singly.

The same kind of pan-pots are also useful for several other purposes of propagation, both to

sow seeds and plant small cuttings, slips, &c. in, of tender exotics, and of various other sorts of curious or particular kinds of plants, both of the green-house, hot-house, and the open ground, in order to have similar culture as the above. These pan-pots are from ten to twelve, or fourteen inches in width, and about six inches deep, having holes at bottom as in the common kind. And another sort of pot of different make from the general kind is sometimes used for planting some kinds of bulbous roots in, for blowing in the apartments of the house: they are narrow and upright, of equal width from bottom to top, six, eight, or ten inches deep, or a little more, and from three to four or five inches in width; and are occasionally used for planting bulbs of the Guernsey lily and some other similar kinds, to blow in autumn and winter, in the windows or on the chimney-piece of the dwelling or sitting-room, or in a green-house, or hot-house, &c., as they appear neat, and admit of being placed close, or in a smaller space than the common pots, one bulb being planted in each; they being previously filled with light sandy earth to near the top. See PLANTING in POTS.

All these several sorts of pots may be obtained at the potteries in the different parts of the kingdom.

In choosing the pots it is necessary to see that they are burnt sufficiently hard, and so perfectly sound as to ring when struck with your knuckles, and that they have all holes at the bottom to discharge the superfluous moisture from the earth about the roots of the plants, the larger sorts having generally four holes, one in the middle of the bottom, and three around the circumference, at equal distances; but the smaller kinds commonly only one in the middle of the bottom.

In respect to the sizes of pots that are proper for the different sorts of plants, it is commonly mentioned in the culture of the plants where any particular sizes are necessary.

Where small pots are advised, it is generally to be understood either as sixties, forty-eights, or thirty-twos, according to the sorts or sizes of the plants that are to be potted.

POTTING OF PLANTS. The operation of placing or planting different sorts of plants, roots, and cuttings, &c., in pots. In this business more care and attention is necessary than is generally bestowed.

POT-HERBS, such as are used for different culinary purposes, consisting of different sorts of the small aromatic kind, and some others. But in a more general signification they comprehend many of the other kitchen garden vege-

tables, but are principally understood to be such as are in request to improve soups, broths, and some other similar culinary preparations, in which, sometimes, several different kinds of small herbs are used in different proportions, both in composition, and singly.

They are chiefly the following sorts: thyme, marjoram, savory, sage, parsley, mint, penny-royal, sorrel, chervil, basil, coriander, dill, fennel, marigold, borage, burnet, tansy, tarragon, chives, leeks, onions, green-beet, white-beet, spinach, celery, endive, lettuce, love-apple, capsicum, and purslane.

Those made use of separately, as salad-herbs, are green and white spinach, to boil as separate dishes; celery, endive and lettuce, as choice salad herbs, and sometimes to stew. But of the above, the thyme, marjoram, savory, parsley, sage, mint, marigold, penny-royal, leeks, celery, and onions, are in the greatest request.

Proper supplies of the different sorts may be raised in the manner directed, under their particular heads. See AROMATIC and KITCHEN GARDEN PLANTS.

PRASIUM, a genus containing plants of the low shrubby exotic evergreen kind.

It belongs to the class and order *Didynamia Gymnospermia*, and ranks in the natural order of *Verticillatae*.

The characters are: that the calyx is a one-leaved perianthium, campanulate-turbinate, erect, bilabiate: upper lip wider, semitrifid, acute; lower lip a little smaller, two-parted: the corolla one-petalled, ringent: upper lip erect, ovate, obsoletely emarginate, concave: lower lip wider, trifid, reflex: the middle segment larger: the stamina have four awl-shaped filaments, pressed to the upper lip, spreading, shorter than the upper lip: two shorter than the two others: anthers oblong, lateral: the pistilum is a quadrifid germ: style filiform, length and situation of the stamens: stigma bifid, acute, with one segment shorter: the pericarpium consists of four berries, at the bottom of the calyx, roundish, one-celled: the seeds are solitary, roundish.

The species are: 1. *P. majus*, Great Spanish Hedge Nettle; 2. *P. minus*, Small Spanish Hedge Nettle.

The first rises with a shrubby stalk two feet high, covered with a whitish bark, and divides into many branches which are declining: the leaves are the size of those of baum, cordate, smooth, blunt, petioled. The flowers come out from the bosom of the leaves in whorls round the stalks: are white, and have large permanent calyxes, cut into five points. It is a native of Spain, &c., flowering here from June to August.

The second species has a shrubby stalk like the former, but rises a little higher: the bark is whiter, the leaves are shorter and ovate, and of a lucid green: the flowers are somewhat larger, and are frequently marked with a few purple spots. It is a native of Sicily.

Culture.—These plants may be increased by seeds and cuttings.

The seeds should be soon on a bed of light mould, in the early spring season, as about April, the plants being afterwards kept clear from weeds, and in the following autumn be removed and placed in the situations where they are to remain, or in pots to be gradually hardened as they advance in growth.

The cuttings should be taken from such plants as are strong, and where the shoots are short and good, and if a joint of the former year's wood be taken to each of them, they succeed better. They should be planted out either in a shady border or in pots in the latter part of the spring season, as about the end of April. When the plants have stricken good root in the borders, they should be removed into the situations where they are to remain, and those in pots into separate ones. These in pots should be placed under a frame during the winter, or in the green-house, where they can have plenty of free air when the season is dry. They only require to be screened from severe frosts. When planted in the open ground they should have a dry poor soil and sheltered situation. These plants afford much ornament in the green-house collections, and among other evergreen shrubs of the more hardy kinds.

PRICKLY PARSNEP. See ECHINOPHORA.

PRICKLY PEAR. See CACTUS.

PRIMROSE. See PRIMULA.

PRIMROSE NIGHTLY, or TREE. See OBNOTHERA.

PRIMROSE PEERLESS. See NARCISSUS.

PRIMULA, a genus containing plants of the low fibrous-rooted herbaceous flowery perennial kind.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Preciae*.

The characters are: that the calyx is a many-leaved involucre, many-flowered, very small: perianthium one-leaved, tubular, five-cornered, five-toothed, acute, erect, permanent: the corolla monopetalous: tube cylindrical, the length of the calyx, terminated by a small hemispherical neck: border spreading, half-five-cleft: segments obcordate, emarginate, obtuse: throat pervious: the stamina have five very short filaments, within the neck of the corolla: anthers acuminate, erect, converging, included: the

Fine leaved Paony

pistillum is a globular germ: style filiform, the length of the calyx: stigma globular: the pericarpium is a capsule cylindrical, almost the length of the perianth, covered, one-celled, opening with a ten-toothed top: the seeds numerous, roundish: receptacle ovate-oblong, free.

The species cultivated are: 1. *P. vulgaris*, Common Primrose; 2. *P. elatior*, Great Cowslip or Oxlip; 3. *P. officinalis*, Common Cowslip or Paigle; 4. *P. farinosa*, Bird's-eye Primrose; 5. *P. longifolia*, Long-leaved Bird's-eye Primrose; 6. *P. cortusoides*, Cortusa-leaved Primrose; 7. *P. marginata*, Silver-edged Primrose; 8. *P. Auricula*, Auricula or Bear's-ear.

The first has a perennial root, growing obliquely, appearing as if bit off at the end, beset with thick reddish scales which are the remains of past leaves, sending down numerous very long round whitish fibres; it has a singular smell, somewhat like that of anise: the leaves are obovate-oblong, about a hand's-breadth in length, nearly upright, tapering to the base, bluish, veiny, wrinkled, smooth above, hirsute beneath, rolled back at the edge when young, slightly waved, unequally notched, the midrib whitish, terminating in a footstalk of a reddish colour, channelled on one side and keeled on the other: the scapes or peduncles numerous, the length of the leaves, upright, round, hirsute, pale green, having awl-shaped bractes at the base, after the flowering is over bending back: the flowers upright, large, sweet-scented: the corolla is of a pale sulphur colour; each of the five clefts obcordate, and marked at the base with a spot of a much deeper yellow: the mouth has a faint rim round it. The flower of the wild Primrose is a pale brimstone colour; but in some places it is found of a purple hue.

The varieties are numerous, being partly wild and partly produced by cultivation. The principal of which are; the Common Yellow-flowered: the White: the Paper-white: the Red: the Double Yellow: the Double White: the Double Red: the Double Pink: the Double Crimson Primrose. It is a native of most parts of Europe, flowering in March and April with the Wood Anemone.

It is observed, that a fine flower of this sort should possess a graceful elegance of form, a richness of colouring, and a perfect symmetry of parts. The properties are mostly similar to those which distinguish the Auricula, in what relates to the stem or scape, the peduncles or flower-stalks, and the formation of the umbel, bunch or thyrse, vulgarly termed the *truss*: the tube of the corolla above the calyx should be short, well filled at the mouth with the anthers,

and fluted termination rather above the eye: the eye should be round, of a bright clear yellow, and distinct from the ground colour: the ground colour is most admired when shaded with a light and dark rich crimson, resembling velvet, with one mark or stripe in the centre of each division of the border, bold and distinct from the edging down to the eye, where it should terminate in a fine point: the petals, technically termed the pips, should be large, quite flat, and perfectly circular, excepting the small indentures between each division, which separate it into five (sometimes six) heart-like segments; and the edging should resemble a bright gold lace, bold, clear and distinct, and so nearly of the same colour as the eye and stripes, as scarcely to be distinguished from it.

The second species has the leaves contracted towards the middle, almost as in the Cowslip: the scapes few, erect, longer than the leaves, many-flowered: the flowers umbelled, pedicelled, the outer ones generally nodding; like those of the Primrose in form and colour, but smaller. From which it is evidently distinguished by its many-flowered scape; as it is from the cowslip by the flat border of the corolla. It is found in the woods and other places in this Country, flowering in April and May.

Martyn remarks that if it be a variety, it is rather of the former than the latter. And Dr. Smith rather inclines to think that it is a hybrid production, or mule from a Primrose impregnated by a Cowslip.

It varies much in the colour of the flowers, but the chief are purple-flowered, red-flowered, gold-coloured, orange-coloured; with various shades of each.

The third has a root like that of the Primrose, but smelling more powerfully of anise: the leaves obovate-oblong, contracted suddenly towards the middle, or rather ovate with the petiole winged, shorter than those of the Primrose by nearly one half, fuller at the edge, which is somewhat folded as well as notched, stronger, of a deeper green, not running so taper at the base, covered on the under side with softer and shorter hair: the petioles smoother, whitish with scarcely any red in them: the scapes few, three or four times longer than the leaves, round, upright, pale, villose: the involucre at the base of the umbel, surrounding the peduncles, consisting of many, very small, concave, pale, acuminate leaflets: the flowers in an umbel, unequally pedicelled, hanging down, generally to one side, full yellow with an orange-coloured blotch at the base of each segment, contracted about the middle of the tube, where the stamens are inserted,

paler underneath, very fragrant. It is a native of Europe, flowering in April and May.

The varieties are the Common Single Yellow Cowslip; Double Yellow Cowslip; Scarlet Cowslip; and Hose, and Hose Cowslip.

The fragrant flowers of these plants make a pleasant wine, approaching in flavour to the muscadel wines of the South of France. It is commonly supposed to possess a somniferous quality.

The fourth species has a perennial root, somewhat præmorse, with numerous, long, perpendicular fibres, and sweet-scented: the leaves obovate-lanceolate, bright green, smooth and even, thickish, here and there turned back on the edges, underneath veined and powdered with white meal: the scape a hand's-breadth or span in height, far exceeding the leaves, round, upright, stiff and straight, of a pale green colour and mealy: the flowers sweet-scented, of a purple yellow colour, in an upright umbel, having at its base a many-leaved involucre, each leaflet of which is awl-shaped, and placed at the base of each peduncle. It is an elegant plant; is a native of many parts of Europe, flowering in July and August.

It varies in the size of the plant, having been found wild a foot and half in height, and in the cultivated plant a tendency to become viviparous, has been observed by Curtis, or to produce one or more tufts of leaves among the flowers of the umbel. In its wild state it seeds readily, and frequently when cultivated: the flowers also vary with different shades of purple, and have been found entirely white.

The fifth bears a great affinity to the fourth, but the leaves differ in form, colour, and mode of growth; when fully grown being twice the length of those of the other: they are not mealy, the under side being as green as the upper, and they have a greater tendency to grow upright: the scape is shorter and thicker: the flowers form a similar umbel, but each is smaller, and in point of colour much less brilliant. Upon the whole, though superior in size, it is inferior to that in beauty. It flowers early in May.

The sixth species, in the wrinkled appearance of its foliage, approaches the first sort; whilst in its inflorescence, the colour of its flowers, and solitary scape, which rises to an unusual height, it bears an affinity to the fourth. In the winter it loses the leaves entirely, and forms a sort of bulbous hybernacle under ground: this circumstance is necessary to be known, as it subjects the plant to be thrown away as dead. It flowers in June and July; and is a native of Siberia.

The seventh, in its farinaceous tendency, ac-

cords with the eighth sort, but is very unlike it in its wild state, the leaves being much narrower: the flowers larger, and of a different colour: the colour of the flowers approaches to that of lilac: it becomes mealy, particularly on the edges of the leaves, between the serratures, where it is so strong as to make the leaf appear with a white or silvery edge. It is a delicate pretty plant, with a pleasing musky smell, and flowers in March and April. It is probably a native of the Alps.

The eighth species has the leaves fleshy, succulent, with the edges mealy, serrated; or entire, according to some—deeply and equally toothed all round, as others affirm; while some say that the young leaves are entire: the adult ones serrate above the middle: the petioles leafy or winged: the leaflets of the involucre unequal, wide, lanceolate or blunt: the flowers very sweet, four or five, in an upright umbel: the calyx one-third of the length of the tube of the corolla, bell-shaped, toothed, mealy, as is also the scape: the tube of the corolla gradually widening upwards, not contracted at the neck: the border concave: the segments emarginate but not deeply, and not cut to the neck: the most common colours are yellow or red, but it is found also purple and variegated, with a white eye powdered with meal: capsule spherical or nearly so, flattened a little at top, of a coriaceous-cartilaginous substance, sprinkled with meal. It is a native of the mountains of Switzerland, Austria, &c., flowering in April and May.

It varies much in the leaves and flowers; as the oblong-leaved; roundish-leaved; broad-leaved; narrow-leaved; green-leaved; white- or meal-leaved; the purple-flowered, of various shades and variegations; red-flowered, with different shades and variegations; yellow-flowered, of different shades; double purple-flowered; double yellow-flowered; variegated purples, &c.

With regard to the properties of a fine auricula, they are these according to Martyn: "The stem should be strong, upright, and of such a height as that the umbel of flowers may be above the foliage of the plant: the peduncles or footstalks of the flowers should also be strong, and of a length proportional to the size and quantity of the flowers; which should not be less than seven in number, that the umbel may be regular and close: the tube, eye, and border should be well proportioned; which they will be, if the diameter of the first be one part, of the eye three, and the whole border six parts or thereabouts: the circumference of the border should be round or nearly so, or at least not what is called starry: the anthers ought to be large, bold, and fill the tube well; and the tube

should terminate rather above the eye, which should be very white, smooth and round, without cracks, and distinct from the ground-colour: the ground-colour should be bold and rich, and regular, whether it be in one uniform circle or in bright patches: it should be distinct at the eye, and only broken at the outer part into the edging: a fine black, purple, or bright coffee-colour contrast best with the white eye: a rich blue, or bright pink is pleasing, but a glowing scarlet or deep crimson would be most desirable, if well edged with a bright green; this, however, can seldom be expected: the green edge is the principal cause of the variegated appearance in this flower, and it should be in proportion to the ground-colour, that is, about one-half of each: the darker grounds are generally covered with a white powder, which seems necessary, as well as the white eye, to guard the flower from the scorching heat of the sun's rays."

It is observed, that all flowers that want any of the above properties are turned out into the borders of the garden or rejected wholly by every good florist; for as there are varieties every year from seeds, the bad ones must make room for their betters: but in some the passion for new flowers so much prevails, that supposing the old flower to be greatly preferable to a new one, the latter must take place, because it is of their own raising.

Culture.—These beautiful plants are raised without much difficulty, by proper care and attention in their management with respect to the parting of the roots, and the planting them out in their due season; they succeed best in a strong soil, and some of them, as the Primrose kind, in a shady situation.

Culture in the Polyanthus kinds.—These are all capable of being increased by seed and the parting of the roots, the former being the only method for obtaining new varieties, or a large supply of plants. The seed should be collected from such flowers as have large upright stems, and which produce many flowers upon the stalk, being large, beautifully striped, open, flat, and not pin-eyed, as from such seed a great variety of good sorts may be expected; care should be however taken that no bad or common flowers stand near them, as they will be apt to debase them, by the admixture of their farina.

The seeds should be sown in boxes or large pots filled with light rich mould. The proper season for this business is in the autumn, or the early spring; but the former is the better, as by sowing then the plants come up well the same year, and are strong and fit to plant out the following spring, and are fine plants for

flowering the second spring. In the first season the sowing should be performed as soon as possible after the seed becomes well ripened, though some advise December as a good time; but when in the latter, or the spring season, it may be done in February, March, or the following month. The seed should be sown over the surface tolerably thick, being covered in very lightly, and the boxes or pots placed where they may have a little of the morning sun, but not by any means the mid-day heats. The plants may be much forwarded by the pots or boxes being plunged in a mild hot-bed; in the spring, when dry, they should be frequently refreshed with water, in very moderate proportions at a time, removing the plants more into the shade as the heat advances, as it soon destroys them. The autumn-sown plants should have a warm situation during the winter, or be protected from frosts or severe weather by glasses or other means.

In the spring or early summer the plants of the different sowings will be sufficiently strong to plant out, for which a bed or shady border should be prepared, and made rich by neat's dung, on which the plants should be set out about four or five inches distant in every direction, care being taken to water them occasionally till well rooted, after which they only require to be kept free from weeds; and when they flower in the following spring the best flowers should be marked, and the rest be removed into the borders or other places for affording variety; and the valuable plants may be removed, when they have finished flowering, into the borders or beds where they are designed to flower and remain, in the same manner as above, watering them slightly till well rooted again. The roots afterwards require to be parted and removed annually, and the earth of the borders renewed, to prevent their degenerating.

It is necessary, in order to keep up a proper stock of plants, to raise new seedling plants every two or three years, as the old plants mostly decline in beauty after the third year.

In the latter method, the roots should be parted in the beginning of the autumn, as soon as the flowering is over, and it may likewise be done early in the spring; but the former is the best time, as the plants get stronger and flower better in the spring.

In performing the work the plants should be taken up out of the ground, and each bunch divided into several slips, not too small, unless where a great increase is wanted, being careful to preserve some root to each slip; they are then to be planted in a fresh dug border, enriched with dung as above, setting them five or six

inches asunder, giving them water directly, and repeating it occasionally till they have taken good root. The approved sorts may in this way be easily preserved.

These plants are observed by the editor of Miller's Dictionary to be very liable to the depredations of snails and slugs, in the spring of the year; the plants and pots therefore should be carefully examined on all sides early in the morning. But their worst enemy is a small red spider or *Acarus*, which in summer forms its web on the under side of the leaves. These little insects, scarcely visible without a magnifying glass, cause the leaves to become yellow and spotted, and eventually destroy the plant: they multiply with such rapidity as to take possession of a whole collection in a very short time. Such plants as appear infected should therefore be immediately selected from the rest, taken up, and soaked for two or three hours in a strong infusion of tobacco water, and then replanted in a fresh soil or compost, and removed to a situation at a distance from the former. But if the whole bed or border be overrun with this insect, it is best to take up all the plants, and, having soaked them, to plant them elsewhere. The bed or border should then be trenched up, and remain fallow to the next season, or be planted with another crop not liable to this calamity.

In their after-management, they are said to "blow at the same time, and require nearly the same treatment, as *Auriculas*, both with respect to soil and situation; they are however more impatient of heat and drought, and more partial to shade and moisture. They may be set in the same sized pots, and in the same compost as the *Auricula*, only with the addition of more loam; or they may be planted on cool shady beds or borders, being very hardy, and seldom perishing in the coldest and wettest seasons, because their parent is a native of this country; but during the heats of summer they are frequently destroyed, unless proper precautions be taken. This dislike of heat seems to indicate," it is added, "that the *Polyanthus* is rather the offspring of the *Primrose*, which requires shade, than of the *Cowslip*, which grows in open pastures; though Mr. Miller seems to regard it as a variety of the latter."

The roots of the wild plants, when they can be procured, may be taken up, divided, and planted out in the autumn, when they will flower in the following spring.

The fourth sort readily seeds in its wild state, and also frequently when cultivated: but it is scarcely worth the pains to raise it from seed, since a strong root may be divided so as to form

many plants; the best time for doing this is in the spring, soon after the leaves are expanded. Each off-set should be placed in a separate pot, filled with two parts of stiffish loam, and one part of light sandy bog earth, watering and setting them in the shade, under a north wall or paling, but not under trees, keeping them there during summer in pans of water, but in the autumn, as the wet season comes on, taking them out of the pans, and either laying the pots on their sides, or placing them during winter under a common cucumber frame, to keep them from immoderate wet, which this plant cannot bear, although it be a native of boggy meadows. In the following if not the same year these plants will blow strong; and they should be thus treated every year, as they require to have their roots frequently parted.

The fifth sort is increased by parting the roots, either in September or at the beginning of March. It is hardy, of ready growth, and will succeed either in the pot or border, by guarding it from the sun in summer and from severe frost and too much wet in winter.

The sixth species, which is yet a rare plant, must be treated with care, as the fifth sort, and may be raised from seeds, or increased by parting the roots; but it is apt to be lost if not well attended to.

The seventh sort is delicate, and should be placed in a pot of stiffish loam, mixed with one-third rotten leaves, bog-earth, or dung, and plunged in a north border, taking care that it does not suffer for want of water in dry seasons; as when thus treated it increases by its roots nearly as readily as the *Auricula*.

Culture in the Auricula kinds.—These plants may all be increased by seeds in order to procure new varieties, and by slipping the roots to increase the approved kinds.

In order to obtain good flowers from seeds, choice should be made of the best flowers, which should be exposed to the open air, that they may have the benefit of showers, without which they seldom produce good seeds: the time of their ripening is in June; which is easily known, by their seed-vessels turning to a brown colour, and opening, being then careful lest the seeds be scattered out of the vessel, as they will not be all fit to gather at the same time.

The proper soil for this sort of seed is good, fresh, light, sandy mould, mixed with very rotten neat's dung, or very rotten dung from the bottom of an old hot-bed; with which the pots, boxes, or baskets in which the seeds are to be sown should be filled; and having levelled the surface very smooth, the seeds should be

sown sifting over them a little rotten willow mould; then covering them with a net or wire, to prevent cats or birds from scratching out, or burying the seeds so as to destroy them. Some persons never cover the seeds, but leave them on the surface, for the rain to wash them into the ground, which is often the best method. The boxes, &c., should then be placed so as to receive half the day's sun, during the winter season; but in the beginning of March be removed, where they may have only the morning sun till ten o'clock; for the young plants now soon begin to appear, which, if exposed to one whole day's sun only, are all destroyed. The proper season for sowing the seed is in the latter end of summer, or beginning of autumn, as about September, but they may be sown in the spring.

During the summer season, the plants in dry weather should be often refreshed with water, never giving them too great a quantity at once. In the July following, the plants will be large enough to remove, at which time a bed must be prepared, or boxes, filled with the above-mentioned soil, in which they may be planted about three inches apart, and shaded when in beds, every day, till they are thoroughly rooted, as also in very hot dry weather; but if they are in baskets or boxes, they may be removed to a shady situation.

When planted in beds, there should be some rotten neats' dung laid about ten inches under the surface, and beaten down close and smooth: this will prevent the worms from drawing the young plants out of the earth, which they generally do where this is not practised. This dung should be laid about half a foot thick, which will entirely prevent the worms getting through it until the plants are well established in the beds; and the roots strike down into the dung by the spring, which makes their flowers stronger than usual: these beds should be exposed to the east, and screened from the south sun as much as is necessary.

In the spring following many of these flowers will show; when such of them as have good properties should be selected, which should be removed each of them into a pot of the same prepared earth, and preserved until the next season, at which time a judgment of the goodness of the flower may be formed; but those that produce plain-coloured or small flowers should be taken out, and planted in borders in the out-parts of the garden, to make a show, or gather for nosegays, &c.; the others, which do not produce their flowers the same year, may be taken up, and set out into a fresh bed, to remain till their properties are known.

VOL. II.

In the second method, the offsets or slips may be taken from the old roots, in the spring or autumn, and be planted into small pots filled with the same sort of earth as was directed for the seedlings, and during the summer season be set in a shady place, and must be often gently refreshed with water, and in the autumn and winter be sheltered from violent rains. In the spring following these plants produce flowers, though but weak; therefore, soon after they are past flowering, they should be put into larger pots, and the second year they will blow in perfection.

In order to obtain a fine bloom of these flowers, the plants should be preserved from too much wet in winter, which often rots and spoils them, letting them have as much free open air as possible; but not be too much exposed to the sun, which is apt to forward their budding for flower too soon; and the frosty mornings, which often happen in March, thereby destroying their buds, if they are not protected; to prevent which, those who are curious in these flowers place their pots in autumn under a common hot-bed frame, where, in good weather, the plants may enjoy the full air, by drawing off the glasses; and in great rains, snow, or frost, be screened by covering them.

About the beginning of February, when the weather is mild, the upper part of the earth in the Auricula pots should be taken off as low as can be, without disturbing their roots, filling up the pots with fresh rich earth, which greatly strengthens them for bloom. As those plants which have strong single heads always produce the largest clusters of flowers, the curious florist should pull off the offsets as soon as it can be done with safety to their growing, to encourage the mother plants to flower the stronger; they should also pinch off the flowers in autumn, where they are produced, and not suffer them to open, that the plants may not be weakened by it. The pots should be covered with mats in frosty weather, during the time of their budding for flower, lest the sharp mornings blight them, and prevent their blowing. When the flower-stems begin to advance and the blossom buds grow turgid, they must be protected from hasty rains, which would wash off their white mealy farina, and greatly deface the beauty of their flowers, keeping them as much uncovered as possible, otherwise their stems will be drawn up too weak to support their flowers, (which is often the case when their pots are placed near walls) giving them gentle waterings to strengthen them, but none of the water should be let fall into the centre of the plant, or among the leaves.

When the flowers begin to open, their pots

should be removed upon a stage (built with rows of shelves, one above another, and covered on the top, to preserve them from wet: this should be open to the morning sun, but sheltered from the heat of the sun in the middle of the day): in this position they will appear to much greater advantage than when they stand upon the ground; for, their flowers being low, their beauty is hid; whereas, when they are advanced upon shelves, they are fully seen. In this situation they may remain until the beauty of their flowers is past, when they must be set abroad to receive the rains, and have open free air, in order to obtain seeds, which will fail if they are kept too long under shelter. When the seed is ripe it should be gathered when it is perfectly dry, and exposed to the sun in a window upon papers, to prevent its growing mouldy, letting it remain in the pods till the season for sowing.

It is observed by the editor of Miller's Dictionary, that "those who are very nice in raising Auriculas, direct the compost to be made of one half rotten cow-dung two years old; one sixth fresh sound earth of an open texture; one eighth earth of rotten leaves; one twelfth coarse sea or river sand; one twenty-fourth soft decayed willow wood; one twenty-fourth peaty or moory earth; one twenty-fourth ashes of burnt vegetables, to be spread upon the surface of the other ingredients. This compost is to be exposed to the sun and air, turned over once or twice, and passed as often through a coarse screen or sieve; then be laid in a regular heap from fifteen to eighteen inches thick, and in this state remain a year, turning it over two or three times, and keeping it free from weeds."

It is added, that "the pots for Auriculas should be hard baked: the inner diameter of the top be six inches and a half, of the bottom four inches, and they should be about seven inches deep, for common-sized blooming plants: but smaller plants and offsets should have smaller shallower pots, and very large plants should have larger pots in proportion; the bottom should have a small degree of concavity, and the hole should be half an inch in diameter: the rims should project about half an inch, in order to take up and remove them with greater ease and safety. The pots should be buried in wet earth, or immersed in water three or four days or a week, before they are wanted, to take off their absorbent property."

In the after-management of the plants, they should be potted annually soon after bloom; curtailing their fibres, if grown very long, and cutting off the lower part of the main root if too long or decayed. The offsets at this season

strike freely, and become well established before winter. The plants should be carefully examined, and where any unsoundness appears, be cut out entirely with a sharp penknife, exposing the wounded part to the sun, and when it is quite dry, applying a cement of bees-wax and pitch in equal quantities, softened in the sun or before a fire. If the lower leaves be yellow or dried up, they should be stripped off in a direction downwards. Having put the hollow shell of an oyster over the hole of the pot, three parts of it should be filled with compost, highest in the middle, placing the plant there, with its fibres regularly distributed all round; then filling the pot up with the compost, adding a little clean coarse sand close round the stem on the surface, and striking the bottom of the pot against the ground or table to settle the earth. The true depth of planting is within half an inch of the lowest leaves, as the most valuable fibres proceed from that part; and the offsets will be thereby encouraged to strike root sooner. When these have formed one or more fibres of an inch or two in length, they may, by means of a piece of hard wood, or by the fingers, be separated with safety, and planted round the sides of a small pot, filled with the same compost, till they are sufficiently grown to occupy each a separate pot: if a small hand glass be placed over each pot it will cause the fibres to grow more rapidly; but if it be long continued, it will draw up and weaken the plants. And in the beginning of May, as soon as the operation of potting is finished, the plants should be placed in an airy, shaded situation, but not under the drip of trees. Here they may remain till September or October, when they should be removed into shelter.

The plants should, in the first favourable weather in February, be divested of their decayed leaves; and by the middle of that month earthing them up; that is, taking away the superficial mould of the pots about an inch deep, and putting in fresh compost, with the addition of a little loam, to give it more tenacity. This contributes greatly to the strength of the plants, and the vigour of their bloom; at the same time it affords a favourable opportunity to separate such off-sets as appear to have sufficient fibre to be taken off at this early season. The pots with these off-sets should be placed in a frame, in a sheltered situation till their roots are established. Though frost, unless it be very rigorous, will not destroy the plants, it will injure them, and perhaps spoil the bloom, especially early in the spring; they should therefore be covered with mats in a severe season. When any plant has more than one or two principal stems, it is ad-

visible to pinch off the smallest and weakest, in order to render the blossoms of that which remains larger and more vigorous. And when the flowers (pips) become turgid and begin to expand, the plants should be selected from the rest, removing them to a calm shady corner, suspending small hand-glasses over them.

In this culture the stages for the pots to stand on whilst in bloom should have a northern aspect, and should consist of four or five rows of shelves, rising one above another, the roof being covered with frames of glass; the tallest blowing plants being placed behind, and the shortest in front. The plants must be regularly watered two or three times every week during the blooming season.

All these plants are highly ornamental; the former in beds and borders, and the latter sorts among curious potted flowering plants.

PRINCE'S FEATHER. See *AMARANTHUS*.

PRINCE'S WOOD. See *CORDIA* and *HAMELIA*.

PRINOS, a genus containing plants of the deciduous and evergreen shrubby sorts.

It belongs to the class and order *Hexandria Monogynia*, and ranks in the natural order of *Dumosaë*.

The characters are: that the calyx is a one-leaved perianth, half-six-cleft, flat, very small, permanent: the corolla one-petalled, wheel-shaped: tube none: border six-parted, flat: segments ovate: the stamina have six awl-shaped filaments, erect, shorter than the corolla: anthers oblong, blunt: the pistillum is an ovate germ, ending in a style shorter than the stamens, and an obtuse stigma: the pericarpium is a roundish berry, six-celled, much larger than the calyx: the seeds solitary, bony, obtuse, convex on one side, angular on the other.

The species cultivated are: 1. *P. verticillata*, Deciduous Winter Berry; 2. *P. glabra*, Evergreen Winter Berry.

The first rises with a shrubby stalk to the height of eight or ten feet, sending out many branches from the sides the whole length: the leaves are lanceolate, about three inches long, and one inch broad in the middle, terminating in an acute point, of a deep green, veined on the under side, alternate on the branches upon slender footstalks: the flowers come out from the side of the branches, single or two or three at each joint: the berries are the size of those of Holly, turning purple when ripe. It flowers in July.

The second species has leaves alternate, petioled, oblong, of a firm texture, smooth, acute: there are commonly two serratures towards the tip: the peduncles axillary, small, commonly

three-flowered. It is of lower growth than the preceding; the leaves are shorter and serrate at their points only. It is a native of Canada, flowering in July and August.

Culture.—In these plants it is effected by seeds, sown soon after they are ripe, or early in the spring, upon a bed of light earth, covering them about half an inch with the same sort of earth: but the seeds which are put into the ground in the autumn will many of them come up the following spring, while those which are kept longer out of the ground, often remain a whole year before the plants appear, as in Holly, Hawthorn, and some others. The seeds may be forwarded in their growth by means of a hot-bed. When the plants have sufficient strength they should be planted out, some in nursery-rows and others in pots. They delight in a moist soil and a shady situation. In hot land they make little progress, and rarely produce any fruit.

They are ornamental, and afford variety in the pleasure-grounds and among potted plants.

PRIVET. See *LIGUSTRUM*.

PRIVET, MOCK. See *PHILLYREA*.

PROTEA, a genus containing plants of the ornamental shrubby exotic kind.

It belongs to the class and order *Tetrandria Monogynia*, and ranks in the natural order of *Aggregatæ*.

The characters are: that the calyx is a common perianth, usually imbricate: scales permanent, various in form and proportion: perianth proper none: the corolla universal uniform: proper one, two or four petalled, with the petals different in figure: the stamina have four filaments, inserted into the petals below the tip: anthers linear: the pistillum is a superior germ, awl-shaped or roundish: style filiform: stigma simple: there is no pericarpium: calyx unchanged.

The species cultivated are: 1. *P. conifera*, Cone-bearing Protea; 2. *P. argentea*, Silvery Protea.

There are several other species that may be cultivated for variety.

The first has a stem erect, three feet high, with branches in whorls and subdivided: the leaves terminated by a concave smooth gland: the cone tomentose ovate, the size of a pea: the branches are in whorls and again subdivided, the leaves elliptic, the cone of flowers tomentose, and the floral leaves concolour.

The second species has a strong upright stalk, covered with a purplish bark, dividing into several branches which grow erect: the leaves broad, shining, silvery, making a fine appearance, when the plant is intermixed with other exotics. It flowers in August.

Culture.—These plants are increased by seeds, procured from the places of their native growth; which, as soon as obtained, should be sown in pots, filled with sandy loam, and placed in a moderate hot-bed; and when the plants are come up, moderate air should be given, or they should be placed in an airy glass case, or towards the front of a green-house; and be afterwards managed as other similar exotics of that kind.

They are also sometimes raised by cuttings, in spring and summer, by the assistance of a hot-bed, in the same manner. They should not have much water afterwards, nor be treated in too tender a manner.

They are ornamental among other potted plants.

PRUNING OF TREES. The operation of occasionally cutting out parts, in order to give them any desired form, and to retrench or reduce irregular and redundant or superfluous growths.

It is particularly necessary to be practised on many sorts of fruit-trees, more especially the dwarf sorts, such as all kinds of wall and espalier fruit-trees; it is also necessary, occasionally, for standard-trees, both dwarfs and half and full standards, and for some sorts annually, as all kinds of wall-trees, espaliers, and most other dwarf or trained fruit-trees; which is done in order to preserve the proper figure, and to keep them within their limited bounds, as well as to promote fruitfulness; but as to common standards, whose heads have full scope of growth every way, they require but very little pruning, except just to retrench any occasional redundancy, ill-growing branches, and dead wood. Wall-trees and espaliers require a general regulation in this way, twice every year: in summer, to retrench the evidently superfluous and ill-placed shoots of the year, and to train in a supply of the most regular ones; and in winter to give a general regulation both for the supply of young wood left in summer, and to the old branches where necessary.

In pruning these sorts of trees, as they have their branches arranged with regularity to the right and left, one above another, in a parallel manner, four, five, or six inches asunder, and forming a regular spread, so as the branches of each tree completely cover a certain space of wall, &c., and as the whole spread of branches constantly send forth every year a great number of unnecessary and useless shoots, each should be limited to a certain space. An annual pruning is consequently necessary to retrench the redundancies, and all irregular and bad shoots, to give the proper bearing branches due room, as well as to confine each tree within its proper limits, consistent with its regular form.

The first pruning for wall fruit-trees, to give the head its first regular formation, is effected by pruning short or heading down in spring all the shoots produced the first year from budding and grafting, and when a year old being mostly pruned down in March, within four or five eyes of the bottom, to throw the sap more into the remaining lower buds, and thus, instead of running up to one stem, to push forth several strong shoots from the lower part the ensuing summer, so as to fill the necessary space of walling and espalier regularly quite from the bottom, which shoots being trained straight and regular in a spreading manner, each at full length all summer; and in the winter or spring following, where a supply of more principal shoots shall seem necessary to form the head more effectually, pruning short also these shoots, each to four or five eyes, when they will throw out the same number of shoots the same year, which, according as they advance in length, should be trained at regular distances at full length during the summer, for the shoots of wall-trees should not in general be shortened in the summer season, as that would cause them to push forth many superfluous unnecessary lateral shoots; though sometimes, in order to fill a vacancy as soon as possible, strong young shoots, by being pinched or pruned early in the season, as May or beginning of June, to four or five eyes, will throw out several proper shoots the same summer. The work of pruning short should be occasionally repeated one or two years, either in general or on particular shoots, as may seem necessary, till a proper set of branches are by that means obtained to give the head of the tree a proper formation; afterwards it may be omitted, except occasionally to any particular shoot to fill a vacant space; but some sorts of wall-trees require almost a general shortening of their supply of shoots, such as peaches, nectarines, &c., which bear only on the young wood, have that of each year shortened, to force out a supply of shoots for future bearing: other sorts of wall-trees and espaliers are not, in the general course of pruning, to be shortened, such as pears, apples, plums, and cherries, which continue bearing in the same wood of from two or three to many years' growth. See **ESPA LIERS**.

When the trees have been thus furnished with a proper spread of branches trained regularly to the wall and espalier, they every year throw out many more shoots than are wanted, or can be converted to use, by some being too numerous, others ill placed, and others of a bad growth; all of which must therefore be regulated accordingly by proper pruning; as the regular figure of the tree, by being well furnished in

every part equally from the bottom to the top of the wall or espalier with proper branches, capable of producing good fruit, is the principal object of this operation.

In performing it the operator should be careful to free the trees of every thing that is superfluous, irregular, or hurtful, both in the summer and winter prunings. Those branches are superfluous, which though good and well placed, are more than wanted or that can be properly laid in, and those irregular which are so ill placed as not to be trained with regularity to the wall or espalier, such as all fore-right shoots, being such as grow immediately from the front or back of the branches in a fore-right direction; and those are hurtful which are of bad growth, such as all very rank or singularly luxuriant rude shoots. The superfluous or redundant growths should of course be thinned by pruning out all that seem to cause confusion; and the irregular and hurtful rank shoots be displaced, cutting all these off quite close to the place whence they proceed, only leaving a proper supply of the regular or best placed side-shoots where necessary, so as to preserve every part well furnished with bearing wood, trained straight and close to the wall or espalier, at equal distances. Some sorts of wall-trees, &c., however, require a general annual supply of young wood, such as peach and all other trees which bear only on the shoots of a year old; others require only an occasional supply of wood, such as apples, pears, &c., and all other kinds that bear on the old wood of from two or three to ten or twenty years old or more; so that the same branches continue in bearing many years, and the trees require only a supply of young shoots now and then to replace any worn out or dead branches. See **SUMMER and WINTER PRUNING**.

This art chiefly consists in being acquainted with the nature of bearing in the different sorts of trees, and in the forming an early judgment of the future event of shoots and branches, as well as other circumstances, for which some rules may be given; but there are particular instances which cannot be judged of but upon the spot, and depend chiefly upon practice and observation.

With regard to the nature or mode of bearing of the different sorts of wall- and espalier-trees, &c. peaches, nectarines, apricots, &c., all produce their fruit principally upon the young wood of a year old; that is, the shoots produced this year bear fruit the year following, and the same of every year's shoots; so that in all these trees, a general supply of the best regular shoots of each year should be every where preserved, both

in the summer and winter prunings, at regular distances quite from the bottom to the extremity of the trees on every side, in such order as to seem coming up regularly one after another; and trained principally all at full length during their summer's growth; but in the winter pruning generally shortened, according to the strength of the different shoots, in order to promote their throwing out more effectually a supply of young wood the ensuing summer, from the lateral eyes, in proper places for training in for the next year's bearing; the fruit-buds being mostly produced along their sides immediately from the eyes, as they rarely form any considerable fruit-spurs, as in the apple, pear, &c., the same shoots producing the fruit and a supply of shoots at the same time for the succeeding year's bearing. All these trees also bear on casual small natural spurs, sometimes arising on the two and three years' wood, one or two inches in length, which are generally well furnished with blossom buds in the proper season; and should be preserved for bearing; always however depending on the main young shoots as the principal bearers.

Vines also produce their fruit always upon the young wood, shoots of the same year arising from the eyes of the last year's wood only, and must therefore have a general supply of the best regular shoots of each year trained in, which in the winter pruning should be shortened to a few eyes or joints, in order to force out shoots from their lower parts only, properly situated to lay in for bearing fruit the following year.

Figs bear also only upon the young wood of a year old, a general supply of it is of course necessary every year; but these shoots should at no time be shortened, unless the ends are dead, as they always bear principally towards the extreme part of the shoots, which if shortened would take the bearing or fruitful parts away. And these trees mostly throw out naturally a sufficient supply of shoots every year for future bearing without the precaution of shortening them.

And as to apple-, pear-, plum-, and cherry-trees, they bear principally generally on spurs arising in the general branches, of from two or three to ten or twenty years old, the same branches and spurs continuing bearing a great number of years, as has been seen, so that having once procured a proper set of branches, in the manner already directed, to form a spreading head, no further supply of wood is wanted than only some occasional shoots now and then to supply the place of any casual worn-out or dead branch as before suggested; these spurs or

fruit-buds are short robust shoots, of from about half an inch to one or two inches long, arising naturally in these trees, first towards the once extreme parts of the branches of two or three years old; and as the branch increases in length, the number of fruit-buds increases likewise; this therefore determines, that in the general course of pruning all these kind of trees, their branches that are trained in for bearing must not be pruned or shortened, but trained at full length, as where shortened it would divest them of the parts where fruit-buds would have first appeared, and, instead thereof, would throw out a number of strong unnecessary wood-shoots, from all the remaining eyes; therefore all the shoots or branches of these trees should be trained principally at full length, and as they advance still continue them entire. When however there is a vacancy, and only one shoot, where two or three may be requisite, pruning or shortening is allowable to force out the proper supply. See DWARF TREES.

In these trees care is necessary to preserve all the proper fruit-buds or spurs, which are readily distinguished by their short, thick, robust growth, rarely exceeding one or two inches in length.

In the course of pruning all sorts of wall- and espalier-trees, all improper and ineffectual shoots and branches, necessary to be displaced, must be taken off quite close to the place whence they arise; which in the summer pruning, if attended to early, while the shoots are young and tender, may readily be rubbed off close with the thumb; but when the shoots become older and woody, as they do not readily break, it must be done with a knife, cutting them as close as possible: all winter pruning should however be performed with a knife.

In pruning in summer, the necessary supply of regular shoots that are left for training in, should never be shortened, unless to particular shoots to fill a vacancy, or to reduce within bounds any too long extended shoots; as by a general shortening in this season, all the shoots so treated would soon push again vigorously from every eye, and run the trees into a perfect thicket of useless wood; therefore all sorts, whether they require shortening in the winter pruning or not, should, in the summer dressing, be layed in at full length.

Summer Pruning.—This is a necessary operation, as in spring and summer wall- and espalier-trees abound with a great number of young shoots that require thinning and other reforms to preserve the requisite regularity and beauty of the trees, and encourage the fruit; and the sooner it is performed, the better; it is therefore advisable to begin in May or early in the

following month, and disburthen the trees in time of all redundant or superfluous growth, and ill placed and improper or bad shoots; which may be then performed with more expedition and exactness than when delayed till after the trees have shot a considerable length and run into confusion and disorder: besides the injury of the fruit is prevented. It is therefore of importance to proceed in this operation early, when the same year's shoots are sufficiently formed to enable you to make a proper choice.

The business now is to thin and regulate the unnecessary shoots, by pruning away the superfluous ones, and all such as are ill-placed and of bad growth, retrenching the most irregular-placed, weakest, and all such as are evidently not wanted for use, and where two or more shoots any where arise from the same eye, clearing all away but one of the best, reserving a sufficiency of the moderately strong and most regular-placed side shoots, and always a leading one at the end of every branch, where it commodiously occurs; all of which should be retained to be regularly trained in to choose from in the winter pruning, leaving more or less in proportion, according to what the trees are, or the mode of bearing, though in all those trees that bear always on the young wood, at least doubly or trebly more shoots should be left in this pruning than what may appear necessary, especially of peaches, nectarines, apricots, vines, figs, &c., as it is highly requisite to reserve plenty of regular young wood in summer, to choose from in winter pruning; to lay in for next year's bearers; but as to apples, pears, plums, cherries, &c., which continue bearing many years on the same branches, only here and there some good well-placed shoots need be left towards the lower parts, or in any vacancy between the main branches till winter; and if then not wanted, be easily retrenched.

Where, however, a tree is in general inclined to luxuriance, it is proper to retain as many of the regular shoots as can be commodiously trained in with any regularity, in order to divide and exhaust the too abundant sap, which causes the luxuriance; as by humouring somewhat the natural inclination of luxuriant trees by leaving plenty of branches and these mostly at full length, they may the most readily be reduced to a more moderate state of growth.

Great attention should always be paid to the lower parts of the trees, as it is frequently the case to find proper shoots arising in places necessary to be trained in, either to supply a present or future vacancy, or as a reserve to replace any decayed or worn-out or other bad branch, so that if moderately strong well-

placed shoots arise in such parts, they are particularly to be regarded at this time; and in winter pruning, such of them as are not wanted may be easily cut out and removed: but all weak trifling shoots should now be taken out.

After having summer-pruned and cleared any tree from all useless shoots, all the remaining proper shoots should be directly, or as soon as they are long enough, trained in straight and close to the wall or espaliers, at full length. When there is any great vacancy in some particular part, it may however be proper to cut or prune one or more contiguous shoots to three, four, or five eyes or buds, in order to promote an emission of laterals accordingly the same season, more effectually to supply the vacant spaces; but all the rest should be trained at full length till winter pruning, when they must undergo another regulation. Those of such trees as require it, as peach, nectarine, &c., should be shortened.

The work of training in the shoots in this season, is performed when against walls, both by nailing, by means of proper shreds and nails, and occasionally, by fastening in the smaller shoots, with little sticks or twigs stuck between the main branches and the wall; and for espaliers, by tying them with small osiers, rushes, or bass strings.

After having thus summer-dressed and trained the trees, it will be necessary to look them occasionally over, in order to reform such branches or shoots as may have started from their places or taken a wrong direction, and according as any fresh irregular shoots are produced, they should be displaced; and likewise as the already trained shoots advance in length or project from the wall or espalier, be trained in close, continuing them at full length during their summer's growth; every thing being kept close and regular, by which the trees will appear beautiful to the eye, and the fruit show itself, and attain its due perfection more effectually.

Winter-Pruning.—In this pruning, a general regulation must be produced both in the mother branches, and the supply of young wood laid in the preceding summer. The proper time for this work is, in most wall-trees, any time in open weather, from the fall of the leaf in November until March. And in performing the business, it is proper to unmail or loosen a great part of the branches, particularly of peaches, nectarines, apricots, vines, and such other trees, as require an annual supply of young wood, and considerable regulation in the general branches.

All the principal or mother branches should

first be looked over, and examined, to see if any are worn out or not furnished with parts proper for bearing fruit, and such branches be cut down either to the great branch from which they proceed, or to any lower shoot or good branch they may support toward their bottom part, leaving these to supply its place; likewise examining if any branches are become too long for the allotted space either at sides or top, and reforming them accordingly, by shortening them down to some lower shoot or branch properly situated to supply the place; being careful that every branch terminates in a young shoot of some sort for a leader, especially in all parts where room to extend them, according as the limited space admits, having the leader either placed naturally at the termination of the branch; or, where too long in any particular parts of the tree, pruned conformably to some lower shoot, &c., so as that it may still terminate in a proper leader, and the extended branches not cut to naked stumpy or stubbed ends, as is often practised by inexperienced pruners. And from the principal or larger branches, pass to the young wood of the year: or, in proceeding both in the occasional reform among the principal or older branches, and more general regulation in the young wood of the year, or shoots of the preceding summer, the above intimations relative to the principal branches should be observed in the pruning in the whole, both on the old and young wood, and be carried on regularly together at the same time, cutting out or retaining according to circumstances; as for instance, in the older wood observing the above particulars, and as below, and in the general supply of young wood, cutting out close all fore-right and other irregular shoots that may have been omitted in the summer-pruning; likewise all very weak shoots, and those of very luxuriant growth, unless it be necessary to keep some to supply a vacant place; then of the remaining regular shoots, selecting a greater or smaller portion to leave either as a general supply for next year's bearing, as is requisite for peaches, nectarines, apricots, vines, and figs; or only in others some occasional shoots, such as in full-trained apple-, pear-, plum-, and cherry-trees, &c., either sometimes to furnish casual vacancies, or to supply the places of any defective or improper branches, or ineffectual bearers, as may casually occur, or that of decayed or dead wood.

But as peach, nectarines, apricots, vines, and figs, always bear principally on the year-old wood, as already noticed, a general supply of young shoots must be left in every part from

bottom to top at regular distances, and, at the same time, some proportional part of the most naked old wood, and of the two preceding years past bearers, be pruned out to make proper room for this requisite young successional supply of future bearers in the following summer, to be now retained in a general manner, both laterally, and as terminals to the general patent branches, which should be pruned accordingly; and mostly all the said supply of the present retained shoots, except the fig, must be more or less shortened according to their situation and strength, to encourage their furnishing more readily a proper supply of shoots in spring and summer for the succeeding year's bearing, as noticed before, leaving the strongest shoots always the longest, as is more fully explained under each of their respective *genera*; but as the figs always bear towards the end of the shoots they must not be shortened.

With respect to the apples, pears, plums, cherries, &c., as they continue to bear on the same branches of from two or three to many years standing, the said bearers must be continued accordingly; and the trees only require an occasional supply of young wood, according as any of the branches become defective, or unfit for bearing, and want removing; which should now be cut out as may seem necessary, training in here and there in proper places some good regular young shoots towards the lower part, and where it may seem necessary, to be coming gradually forward to a bearing state, to be ready to replace worn-out and other useless branches, to be cut out, as they may occur: and of the young wood, selecting what may appear necessary of the best well-placed shoots, and the superabundance, or those not wanted for that purpose, together with all irregular-placed shoots, rank luxurians, and other ineffectual growths, should be now cut clean out, close to whence they originate, not leaving any spur or stump, as every one would push out several strong unnecessary shoots the next spring, to the prejudice of the trees and fruit: particular regard should be paid to preserve the shoots at the termination of all the already trained branches entire, but not more than one to terminate each branch; preserving also carefully all the proper fruit-spurs, taking care that the supply of young wood be occasionally reserved, and the branches in general of these trees be trained in at full length, and continued so in future, as far as the limited space will admit: and according as any extend above the wall or espalier or any where beyond their proper limits, they be pruned down with discretion to some convenient

bud, or lateral shoot, or lower branch, which should be trimmed entire.

In this pruning, as in the summer dressing, it is of importance to have a strict eye to the lower parts of wall-trees, &c., to see if there is any present vacancy or any that apparently will soon happen; in which cases, if any good shoot is situated contiguous, it should be trained in either at full length, or shortened to a few eyes to force out two or more shoots if they shall seem necessary; for precaution should ever be observed in taking care to have betimes a sufficient stock of young wood coming forward to fill up any casual vacancy, and substituting a new set of branches in place of such as are either decayed or stand in need of retrenchment.

In wall-trees and espaliers there are sometimes many large disagreeable barren spurs, consisting both of old worn-out fruit spurs, and of clusters of stumps of shortened shoots projecting considerably from the branches, occasioned by unskilful pruning when retrenching the superabundant and irregular shoots, which, instead of being cut out close, are stumped off to an inch or two long, and in the course of a few years, form numerous barren stumps, and very little fruit, the trees appearing like a stumped hedge. In this season of pruning, (in this case) it is proper to reform them as well as possible by cutting all the most disagreeable stumps clean out close to the branches, leaving these at full length, especially in apples, pears, &c., and reserving an occasional supply of young wood in different parts: thus in two or three years such trees may be reduced to a regular figure and a proper state of bearing.

It is observed that bad pruning ruins many a good tree, as is observable in numerous gardens, where the wall-trees and espaliers appear as just described, pruned every year, yet never producing any tolerable crop of fruit.

Severe injudicious pruning in strong wood is greatly prejudicial to the health of some sorts of stone-fruit-trees, by causing them to gum and soon decay. Plums and cherries, in particular, are often greatly damaged by a too severe discipline of the knife, these being very liable to gum by large amputations: it is therefore of importance to attend to these trees well in the summer-pruning, to retrench all the superfluous and irregular shoots betimes in the summer while quite young, and pinch others occasionally where wood is wanted to fill vacancies, so as to require but little pruning out of large wood in winter.

A general nailing, &c., must every year be performed, according as the pruning advances,

as it is proper that every tree, as soon as pruned, be directly nailed to the wall, or if espaliers, tied or nailed to the treillage, being careful in the winter pruning, as the work of nailing, &c., will require to be performed more or less upon all the branches, to train them with great regularity, nailing them along horizontally, as straight and close as possible; never crossing any of the branches, but training them distinctly and parallel four to five or six inches asunder, or in proportion to the size of the leaves and fruit of the different sorts, making the opposite branches of each side arrange equally in the same manner and position.

Pruning of Standard Trees.—Standard fruit-trees require but very little pruning; for, as their branches have full scope above to extend themselves every way, they must not be shortened: besides, as the standard fruit-trees, consisting principally of apples, pears, plums, and cherries, bear fruit on natural spurs arising towards the upper parts of the branches, this determines that they must not be shortened, nor any other pruning be practised than just to reform any great irregularity, &c., in them. In these trees, the first occasional pruning necessary is the first two years of their growth, in order to form their heads somewhat regular, by retrenching any irregular shoots; and when designed to have them form more regular spreading heads, to prune the first shoots, when a year old, down to four or five eyes, in order to force out lateral shoots from these lower buds the following summer, to give the head a proper formation. After this, the branches should be suffered to take their natural growth, except that, if, while the trees are young, any very luxuriant shoots ramble away considerably from all the others, and draw most of the nourishment, it is proper to prune them, either by retrenching entirely very irregular ones, or shortening others to some regularity, to branch out consistently with the requisite form of the head of the tree; but except in such cases of reducing irregularities, the heads of all kinds of standards always should be left to branch away as fast as possible, both in length and laterally, agreeably to their natural mode of growing; and they will naturally furnish themselves abundantly with bearing wood.

In standard fruit-trees of some years' growth, as irregularities and disorder will occasionally happen, they should be regulated a little by pruning out the most conspicuously irregular and redundant growths in the winter season.

For instance; where any considerable branches grow right across others, or in any other awkward direction, to incommode or cause confusion, or much irregularity in the head, they

Vol. II.

should be retrenched close; likewise any branch that rambles considerably from all the rest, should be reduced to order, by cutting it down to some convenient lower branch, so as to preserve some regularity. Where the head is considerably crowded with wood, let the worst of the redundancy be thinned out as regularly as possible, cutting them close to their origin; and as sometimes very vigorous shoots arise in the heart of the tree, or towards the bottom of the main branches, growing upright, and crowd the middle of the head, they should be constantly retrenched to their very bottom; cutting out also any very cankered parts, and all decayed wood; and clearing off all suckers from the root and stem. The standard trees thus disburthened from any considerable irregularities and confusion, so as all the proper branches have full scope to spread free and easy in their natural manner, will not fail to repay the trouble in the superior quality of their future fruit. See ORCHARD-TREES.

Pruning of Forest Trees, &c.—With respect to pruning of forest and ornamental trees, flowering shrubs, &c., it is very inconsiderable. Forest trees, &c., must be suffered to run up as fast as possible, so that their heads should not be shortened; all that is necessary is, to prune off the lateral branches occasionally from the stem; or, if while young, any lateral shoot of the head, which is of a very rude rambling growth; but otherwise suffering the top and general branches of the head to remain entire, and take their own natural growth; only pruning the lower stragglers occasionally. It is however very improper to trim up the stem too high, as often practised to forest trees, as scarce to leave any upper branches to form a head: never, therefore, trim the stem much higher than the full spread of the principal branches, as a full head is both ornamental and essentially necessary to the prosperity of the tree. See PLANTING.

And as to the shrub kind, they should, for the general part, take their own growth at top; and only be pruned occasionally in any lower stragglers, from the inferior part of the stem, or any very irregular rambling shoot of the head, and all dead wood. Except in these cases, their heads mostly should be suffered to shoot in their own way, according to their different modes of growth, in which they will appear always the most agreeable. Where, however, it is required to keep shrubs low, they must be regulated, as convenient; with the pruning-knife, as being more proper than the garden-shears, which should never be used in that business to shrubs and trees in rural growth.

The particular method to be followed with

each sort of tree has been shown under the proper head to which it belongs.

Pruning Implements.—For the purpose of general pruning, several implements are necessary, such as pruning-knives, saws, chisels, hand-bills, hatchets, &c. Two or three different sizes of knives are requisite, in order to prune neatly; a strong one for cutting out larger branches, shoots, &c., and a small one for the more exact pruning among the smaller branches and shoots of peach and nectarine trees, &c. These knives are generally made curving at the point, and they should not be too long, broad, and clumsy, but have rather a shortish narrow blade, and but very moderately hooked at the point, for when too crooked they are apt to hang in the wood, and not cut clean; it is also proper to be furnished with a strong thick-backed knife, to use by way of a chisel occasionally, in cutting out any hard stubborn stumps, &c., placing the edge on the wood, and with your nailing hammer striking the back of it, and it will readily cut through even and smooth. A long knife with a concave edge, and a pruning-knife with a convex edge, are also recommended by Mr. Forsyth.

Hand-pruning saws are likewise proper for cutting out any large branch too thick and stubborn for the knife: these should be of moderate sizes, one being quite small and narrow, in order to introduce it occasionally between the forks of the branches, to cut to exactness.

And as saws generally leave the cut rough, it is proper to smooth it with a knife or a pruning-chisel.

The pruning-chisels are necessary to use occasionally, both to cut off any thick hard branches and large hard knotty parts, or stumps, and to smooth cuts in large branches, &c., after a saw; they should be flat, and from about one to two inches broad: sometimes large strong chisels, fixed on a long pole, are used in pruning or lopping branches from the stems of high standard forest trees, one man holding the chisel against the branch, while another, with a large mallet or beetle, strikes the end of the pole. A hand-bill and hatchet are also necessary to use occasionally among larger kinds of the standard trees.—See TOOL.

All these pruning-tools, in their proper different sizes, may be had at the cutlery shops, and of the ironmongers, and many of the nursery and seedsmen.

PRUNUS, a genus containing plants of the fruit-tree, flowering and evergreen shrubby kind.

It belongs to the class and order *Icosandria Monogynia*, and ranks in the natural order of *Pomaceæ*.

The characters are: that the calyx is a one-leaved perianth, bell-shaped, five-cleft, deciduous: segments blunt, concave: the corolla has five petals, roundish, concave, large, spreading, inserted into the calyx by their claws: the stamina have twenty to thirty awl-shaped filaments, almost the length of the corolla, inserted into the calyx: anthers twin, short: the pistillum is a superior, roundish germ: style filiform, the length of the stamens: stigma orbicular: the pericarpium is a roundish drupe: the seed is a nut, roundish, compressed, with sutures a little prominent.

The species cultivated are: 1. *P. domestica*, Common Plum Tree; 2. *P. insititia*, The Bullace Plum Tree; 3. *P. Armeniaca*, Apricock or Apricot Tree; 4. *P. Cerasus*, Common or Cultivated Cherry Tree; 5. *P. Avium*, Small-fruited Cherry Tree; 6. *P. Padus*, Common Bird Cherry Tree; 7. *P. rubra*, Cornish Bird Cherry Tree; 8. *P. Virginiana*, Common American Bird Cherry Tree; 9. *P. Canadensis*, Canadian Bird Cherry Tree; 10. *P. Mahaleb*, Perfumed Cherry Tree; 11. *P. Caroliniana*, Evergreen Bird Cherry Tree; 12. *P. Lauro-cerasus*, Common Laurel; 13. *P. Lusitanica*, Portugal Laurel.

The first is a tree of a middling size, growing to the height of fifteen or twenty feet, branching into a moderately-spreading head: the leaves are on short petioles, which have one or two glands towards the end; they are slightly serrate and smooth; when young convoluted or coiled, and pubescent underneath: the peduncles short, commonly solitary: the calyx erect: the petals white, obovate: the drupe is an oblong spheroid, swelling a little more on one side and there grooved, of a blue colour, with a bloom on it: pulp yellowish, tender: the shell bony, ovate, pointed at both ends, and compressed: it loves a lofty exposure, and is a native of Asia and Europe. The cultivated garden Plums are all derived from this species.

The varieties of garden and orchard Plums are very numerous, differing in the form, taste, colour and substance of the fruit; but those mostly cultivated in this country are the following, according to Mr. Forsyth, and the times at which they ripen:

The Jaunhative, or White Primordian, which is a small plum, of a yellow colour, and mealy: it ripens in the latter end of July, or beginning of August: one tree of this sort will be sufficient for a garden of the common size. The Early Damask, which is commonly called the Morocco Plum, and which is middle-sized, and the flesh good: it ripens about the beginning of August, or sometimes a little later. The

Little Black Damask, which is a rich fruit, a good bearer, and becomes ripe about the latter end of August, or thereabouts. The Great Damask Violet of Tours, which is a fine rich plum of a blueish colour, and becomes ripe in August. The Red Orleans, which is large, of a rich juice, and becomes ripe in the latter end of August. The Fotheringham, which is an excellent plum, of a dark red, and the juice rich: there is hardly any plum that excels it, according to the opinion of some. The Blue Perdrigon, which is of a very good taste, and ripens in August. The White Perdrigon, which is a pretty good fruit, and has a sweetish taste mixed with tartness: it ripens in the beginning of September. The Red Imperial, or Red Bonum Magnum, which is a great bearer, and mostly used for baking: it is ripe about the latter end of September. The White Imperial Bonum Magnum, or Egg, White Holland, or Mogul, which is a large fruit, and, like the Red, mostly used for baking: it is a great bearer, and ripens about the beginning of October. The La Royale, which is a fine plum, equal to the Green Gage, but a shy bearer: it is of a red colour, and ripens in the latter end of September. The Little Queen Claudia, which is a small rich fruit, becoming ripe in September. The Large Queen Claudia, or Dauphiny, which is an excellent plum, of a yellowish green, and ripens about the beginning of October. The Green Gage, which is of an exquisite taste, and eats like a sweetmeat: its colour and size sufficiently distinguish it from any other: it ripens in August and September: it has several sub-varieties, all of which are of good qualities. The Drap d'Or, which is a good plum, and a plentiful bearer: it is ripe about the latter end of September. The Chester, which is rich, and a great bearer: it is ripe about the latter end of September. The Apricot, which is large and sweet, and is ripe in the beginning of October. The Maître Claud, which is a large round whitish plum: the juice is very brisk, though sweet: it is accounted among the best white plums that we have, and ripens about the beginning of October. The Myrobolanus, or Cherry Plum, which is a middle-sized sweet fruit, and ripens about the beginning of September: this plum is frequently planted for ornament, as it blossoms early. The La Mirabelle, which is of an amber colour, and small, but full of juice, and excellent for sweetmeats: it bears well, and becomes ripe about the beginning of September. The Brignole, which is esteemed the best plum of any for sweetmeats: the flesh is dry, but of a rich flavour: it is ripe about the latter end of September. The Red Diaper, which is large, and of a very high flavour: it

ripens about the beginning of September. The Saint Catharine, which is one of the best, and is much used for confectionary; it is also very good for the table, having a rich sweet juice; and is a good bearer, hanging the longest of any upon the tree: Mr. Forsyth says, he has had them in gathering six weeks: it ripens about the latter end of September. The Imperatrice, or Empress, which has an agreeable flower, and ripens about the middle of October: it is one of the latest plums, and should not be gathered till it begins to shrivel; it will then eat like a sweetmeat, and make a great addition to the table in the latter end of October and beginning of November. Monsieur's, or the Wentworth, which is a large fruit resembling the Bonum Magnum: it ripens about the beginning of October, and is good for preserving, but too sharp to be eaten raw. The Winesour, or Yorkshire, which is one of the best for preserving: it is ripe in October. The Damson, of which a fine large sort from Shropshire, raised from suckers or stones, is an abundant bearer, of a rich flavour, and good for baking or preserving: it ripens in the latter end of September, and continues till near the latter end of October to be good and fit for use.

To these Mr. Forsyth adds the following list: The Admirable, the Black Damascene, the Black Pear, the Blue Matchless, the Damas Noir de Tours, the Don Carloses, the Double-flowered, the Early Blue Primordian, the Early Red Primordian, the Early Amber, the Early Tours or Precoce de Tours, the Early Violet, the Early Orleans, the Fine Early Plum, the Jacinthe or Hyacinth, the Koa's Imperial, the La Prune Suisse, the La Prune Valeur Valentia, the Matchless, the Mageron, the Muscle, the Persian, the Red Queen Mother, the Royal Pea, the Royal Dauphin, the St. Julian, the Semina, the Small White Damascene, the Spanish Damascene, the Striped-leaved, the True Prune, the Verte-dock or Ver-dock, the Whitton or Nutmeg, the White Bullace, the White Orleans, the White Pear, the White Perdrigon.

The following sorts are recommended by the same writer as proper for a small garden: The Jaunhative, the Early Damask, the Orleans, the La Royale, the Green Gage in different sorts, the Drap d'Or, the Saint Catharine, and Imperatrice; the Magnum Bonum for baking; and the Winesour for preserving.

The second species is a tree which grows twelve or fifteen feet high or more: the branches are generally thorny: the leaves on short petioles, ovate attenuated at the base, serrate, villose underneath: the calyx is almost upright: the petals white, obovate: the drupe roundish.

The fruit is acid, but so tempered by sweetness and roughness as not to be unpleasant, especially after it is mellowed by frost. It is a native of Germany, flowering in April.

It varies with black, and white or rather wax-coloured fruit; and also with a red, bitter, unpleasant fruit.

The third is sufficiently distinguished by its broad roundish leaves drawn to a point at the end, smooth, glandular at the base in front, where they are sometimes slightly cordate, and unequal, that is, one side longer than the other: the edge is finely serrate: the petiole is from half an inch to an inch in length, commonly tinged with red: the vernant leaves convoluted, rolling upwards more or less; the leaves have a disposition to this at all times: the flowers are sessile, white tinged with the same dusky red that appears on the petioles: the fruit is round, yellow within and without, firmer than plums and most peaches, inclosing a smooth compressed stone, resembling that of the plum. It is a native of Asia.

There are many varieties of this; but the following are the most commonly cultivated, according to Mr. Forsyth: The Masculine, which is a small roundish fruit: it is the earliest of all the apricots, ripening about the latter end of July; and is chiefly esteemed for its tart taste: when fully ripe, it is of a red colour towards the sun, and of a greenish yellow on the other side. The Orange, which is pretty large, but rather dry and insipid, and fitter for tarts than for the table: it is of a deep yellow colour when ripe, which is about the latter end of August: this is considered as the best for preserving. The Algiers, which is a flatted-oval-shaped fruit, of a straw colour, juicy, and high-flavoured: it ripens about the middle of August. The Roman, which is larger than the Algiers, rounder, of a deep yellow, and not quite so juicy: it is ripe about the middle or latter end of August. The Turkey, which is larger, and of a deeper colour than the Roman; its shape more globular, and the flesh firmer and drier: it ripens about the latter end of August. The Breda, (brought from thence to England,) which is originally from Africa: it is large, round, and of a deep yellow colour; the flesh is soft and juicy: it is an excellent fruit, especially if ripened on a standard, becoming ripe about the latter end of August. The Brussels, which is held in very great esteem on account of its bearing so well on standards, or large dwarfs: it is of a middling size, red towards the sun, with many dark spots; and of a greenish yellow on the other side: it has a brisk flavour, is not liable to be greasy or doughy, and is preferred by many to the Breda; but when

the Breda is planted as a standard, the fruit is more juicy and of a richer flavour: it ripens in August on a wall, but not before the latter end of September on standards. The Moor-Park, called also Anson's, Temple's, and Dunmore's Breda, which is a fine fruit, and ripens about the latter end of August. The Peach, which was introduced from Paris, by his Grace the Duke of Northumberland, at Sion-house, in 1767: it is the finest and largest of all apricots, and is generally thought to be the same as the Moor-Park; but upon a minute examination the leaves will be found to differ: it ripens in August. The Black, which has been very lately introduced, by Sir Joseph Banks, from France, in which country it is highly esteemed. It is observed, that "the trees that Sir Joseph planted in his gardens at Spring Grove, near Hounslow, bore fruit last season, (1792) for the first time in this country; but, in consequence of the wet and unfavourable weather, it did not arrive at perfection. It ripens about the second week in August."

To the above list Mr. Forsyth has added the following: The Great Apricot, the Holland Apricot, the Provence Apricot, the Alberge, the Angoumoise, the Blotched-leaved, the Nancy Apricot, which has a fine large fruit; the Dutch Apricot, the Grover's Breda, the Persian, the Royal Orange, the Transparent, the Portugal Apricot, which has a small fruit.

The following are advised as proper for small gardens, in order to have regular successions of fruit: The Masculine, the Roman, the Orange, the Breda, and the Moor-Park.

The fourth species is a tree that has ash-coloured, shining, roundish branches: the leaves petioled, ovate or ovate-lanceolate, acuminate, unequally serrate, veined; the younger ones folded together flat, and more or less pubescent underneath: the stipules toothed, glandular: the umbels leafless, few-flowered, nodding: the calyx reflex: the petals white: the drupe red and acid. It differs from the plum in having the stone nearly globular, with the kernel of the same shape. It is a native of Asia and Europe.

It loves a sandy soil and an elevated situation.

The varieties are numerous; but the following are those most in cultivation, according to the above author: The Small May Cherry, which is the first ripe, and requires a good wall: one or two trees of this kind may be sufficient for a large garden: it is ripe in June. The May Duke, which comes in about the same time as the former, but is larger: it is an excellent cherry, and bears well against a wall. The Archduke, which, if permitted to ripen properly, is an excellent cherry: it becomes ripe

in June and July. The Hertfordshire Cherry, which is a sort of Heart, but firmer and of a finer flavour than Hearts in general: it does not ripen till the latter end of July, or beginning of August, which renders it the more valuable, as it succeeds more early Cherries. The Bleeding Heart, or Gascoign's, which is a very large cherry of a long form, and dark colour: it has a pleasant taste, and ripens in the latter end of July. The Harrison's Heart, which is a fine cherry: it was introduced from the East Indies by Governor Harrison, grandfather to the present Earl of Leicester, and first cultivated at his seat of Balls in Hertfordshire: some of the trees, Mr. Forsyth is informed, he presented to George the First; and they are at this time in a flourishing state, bearing fine fruit, in Kensington Gardens: it is ripe in July and August. The Black Heart, which is a fine cherry, but too well known to require any description. The Morello, or Milan, which is a very fine fruit when kept till the month of October, and makes a very great addition to the dessert at that time of the year: it is the best cherry that we have for preserving, and for making cherry-brandy. The Carnation, which takes its name from its colour, being red and white: it is a large round cherry, but not so sweet as the Duke Cherry: it ripens in the latter end of July. The Yellow Spanish, which is of an oval shape and amber colour, and is a sweet pleasant fruit: it is ripe in August and September. The Corone, or Coroun, which resembles the Black Heart, and which is an excellent fruit, and a good bearer, ripening about the beginning of August. The Lukeward, which comes in soon after the former, and is also a fine pleasant fruit, and a good bearer: it ripens in the beginning of August. The Graffion, which is supposed by many to be the same with Harrison's Heart; but, upon a close examination, Mr. Forsyth finds it to be a different cherry: its flesh is firmer and the stone flatter: it ripens in July and August. Ronalds's Large Black Heart, which was introduced into this country in the year 1794 from Circassia, is a fine large cherry, a great bearer, and valuable as a forcing sort: it is well worth cultivating, ripening in the beginning of July. The Fraser's Black Tartarian, which is a fine large fruit. The Fraser's White Tartarian, which is white and transparent. These cherries are excellent bearers, but particularly the Black kind: the fruit is of a fine brisk flavour, and they ripen early. The Luidie Gean, cultivated at Lord Viscount Duncan's, near Dundee, which is black, and almost as large as a Black-Heart Cherry: Mr. Forsyth says, "it is now common in the nurseries about Edinburgh; and

that Messrs. Gray and Wear have had it for some years in their nursery at Brompton-park." The Transparent Gean, which is a small delicious fruit.

To these the following list is subjoined: The Amber Heart; the Black Mazard; the Churchill's Heart; the Double-blossomed; the Flemish Heart; the Gross Goblet; the Holman's Duke; the Jeffrey's Royal; the Kensington Duke; the Large Spanish Cherry; the Late Large Morello; the Montmorency; the Ox Heart; the Purple Heart; the Red Heart; the Spanish Black; the South's Large Black; the Swedish Black Heart; the Tradescant's; the Turkey Heart; the Weeping; the Wentworth Heart; the White Heart.

The following are recommended as proper for a small garden: The May Duke; the Large Duke Cherry; the Archduke; the Black Heart; the Harrison's Heart; the Ox Heart; the Turkey Heart; and the Kensington Duke Cherry.

The fifth grows to be a large tree, fit for timber, and is frequently found growing as such in the woods. It is supposed to be a native of England.

The only varieties raised by seeds, from this, are the Black Coroun, and the Small Wild Cherry; of which there are two or three sub-varieties, differing in the size and colour of the fruit.

It is observed by the editor of Miller's Dictionary, that "the wild cherries are proper to plant in parks, because they grow to a large size and make beautiful trees. In spring, when they are in flower, they are very ornamental; the fruit is good food for birds; and the wood is very useful for turners. These trees thrive in poor land better than most other sorts. The French often plant them for avenues to their houses, on poor land; they also cultivate them in their woods, to cut for hoops; and the stones are generally sown for raising stocks, to graft or bud other Cherries upon, being of quicker growth and of longer duration." It is added that "the Garden Cherry grows only about fifteen or twenty feet high, whereas this attains forty or fifty feet in height, with a more erect and lofty head."

The sixth species rises to the height of ten or twelve feet, and, if permitted to stand, will have a trunk of nine or ten inches in diameter. The branches grow wide and scattering, and are covered with a purplish bark: the leaves ovate-lanceolate, alternate, slightly serrate: the flowers are in long loose bunches from the side of the branches: the petals white, much smaller than those of the Cherry: the flowers ranged alternately, each on a small pedicel: they have a strong scent, which is very disagreeable to most persons. They appear in May, and are suc-

ceded by small roundish fruit, at first green, afterwards red, but when ripe black; inclosing a roundish furrowed stone or nut, which ripens in August. It is a native of most parts of Europe.

It is commonly propagated in the nurseries as an ornamental tree or shrub, growing well in woods, groves or fields, but not in a moist soil. It bears lopping, and suffers the grass to grow under it. It is sometimes called the Cluster Cherry Tree.

The seventh rises with a straight upright stem more than twenty feet high: the branches are shorter, and closer together than those of the sixth sort, and naturally form a regular head: the leaves are shorter and broader, and not so rough: the flowers grow in closer shorter spikes, standing more erect: the fruit is larger, and red when ripe. It flowers a little later than the sixth sort, as in May and June; and the fruit ripens in August. It grows naturally in Armenia.

The eighth species rises with a thick stem from ten to thirty feet high, dividing into many branches, which have a dark purple bark: the leaves are ovate, alternate, on short footstalks, of a lucid green, slightly serrate, and continuing in verdure as late in the autumn as any of the deciduous trees: the fruit is larger than that of the preceding, is black when ripe, and is soon devoured by birds: the wood is beautifully veined with black and white, and polishes well. It is a native of Virginia and other parts of North America.

In the ninth the branches are even: the leaves less rigid than in the others, finely serrate, green on both sides, but manifestly villose to the touch, and ending in the petiole at the base. It is a native of North America.

The tenth species is a low crooked tree: the wood is red, very hard, and sweet-scented: the leaves wide and pointed, approaching to those of the wild pear: the flowers white: the fruit black, yielding a bitter purple juice, the stain of which is not easily effaced: the stone is smooth, round, and a little flattened on the sides; inclosing a bitter perfumed kernel. The birds are very fond of the fruit. It is a native of Germany, Switzerland, Austria, &c. flowering in April and May. Ray calls it Rock Cherry.

The eleventh is rather a shrub, if we judge from its growth in this climate: the stalk does not rise more than three feet high, but sends out lateral branches spreading on every side, covered with a brown bark: the leaves are alternate on very short footstalks, near two inches long and three-quarters of an inch broad, with small acute indentures on their edges; they are of a lucid green, continuing their verdure all

the year. It is a native of South Carolina, flowering in May.

The twelfth species is a shrub sending off long spreading branches, covered with a smooth brown bark: the leaves are elliptical or obovate, slightly serrate, alternate, upon strong, short foot-stalks: the flowers on short axillary peduncles: the calyx ovate; segments reflex, pointed: the petals small, white: the filaments about eighteen: the fruit resembling a black cherry, both in its external and internal structure. It differs from the Portugal sort in having the twigs and petioles green, whereas in that they are reddish brown. The leaves are of a yellowish green, whereas the green on the upper surface is very dark in that; they are also much wider in proportion and elliptical, but in that they are rather lanceolate; they are both toothed about the edge, but this more slightly, and the serratures of this are very harsh to the touch, as if they had prickles at the end: the veins are much more prominent at the back of the leaves in this; in that the leaves are commonly repand along the edge; but in this they are flat, except that the edge is a little bent back. The leaves in both are acuminate but end bluntly, and they generally bend down at the point. The young leaves are inclined to fold together upwards, like those of the Cherry, in this; but in that they are revolute, leaving a wide longitudinal hollow above: the old leaves are generally imperfect at the end, and in this are sometimes retuse or emarginate. The glands, which are obsolete, are placed on each side the midrib, about half an inch above the petiole. It flowers in April, and is a native of the Levant, of Caucasus, &c.

The thirteenth rises with a strong tree-like stem to the height of twenty feet or more, sending out many branches on every side, which have a shining purplish bark: the leaves are on short foot-stalks, of a lucid green, about three inches long, and an inch and half broad in the middle; they are sometimes slightly serrate, but generally entire: the flowers are produced in long bunches from the side of the branches, white, and shaped like those of the twelfth sort: the berries are oval, pulpy, at first green, then red, and when ripe very dark purple; smaller than those of the last sort and narrower at the end; enclosing an oval stone, like that of the Cherry, but more pointed at the top. It flowers in June; and is one of the most beautiful evergreen shrubs, having a fine appearance in long racemes of fine white flowers. It was introduced from Portugal.

Culture in the Plum Kind.—It is obvious that all the varieties were first obtained by seed, or

the stones of the fruit; and the approved kinds acquired in this manner were afterwards multiplied by grafting and budding; as they do not continue the same sorts from seed, for from the seed of one tree many different sorts may be produced, and probably none like the mother-tree, and very few that afford fruit worth eating: but when in possession of any approved sorts, they may be multiplied at pleasure, by ingrafting shoots or buds of them into any kind of Plum-stocks. Of course the mode of increasing these trees is, by grafting, budding, and occasionally by layers; but the two former are the most usual methods of practice.

The two first modes may be performed upon stocks of any sorts of the Plum-kind, which have been raised from the stones, sown in autumn in beds of good earth, about two inches deep; and when the plants are a year old, planted out in nursery rows two feet and a half asunder; when, after having from one to two or three years' growth, they are in a fit state for grafting or budding with the desired sorts; which is performed in the usual way, either low in the stock for dwarfs, or at several feet height for standards. See GRAFTING and INOCULATION.

These trees may be trained either as dwarf wall trees, espaliers, or as standards and half standards.

When the first shoots from the graft or bud are one year old, those of the trees designed as dwarfs for walls, &c. should be headed down within five or six inches of the bottom, particularly the budded trees, in order to force out laterals from the lower eyes, so as to furnish a proper set of branches, proceeding regularly from the bottom of the tree, to cover every part of the wall or espalier. With regard to the standards, their first shoots may either be suffered to run and branch in their own way, or headed to a few eyes, if it seem necessary, to force out lower laterals to give the head a more regular spreading form, afterwards letting them all take their own natural growth.

When the trees raised in either of these modes are from one to two or three years old, they are of a proper size for being finally planted out in the garden, or other place; though trees which are much older may be safely removed; but the younger they are planted where they are to remain, the sooner and more firmly they establish themselves, and form for bearing.

In the layer method, which is only practised occasionally, the business may be performed any time from November till March, choosing the last summer's shoots, and laying them down by *slit-laying*; when in one year they will be rooted, and must then be separated, and planted in nur-

very rows, being trained either for dwarfs or standards as may be required.

And the Double Blossom, the Striped varieties, and the Stoneless kind, are all increased by budding or grafting upon any kinds of Plum-stocks, either for dwarfs, or half or full standards.

The Bullace kinds are capable of being increased by sowing the berries or stones an inch deep in a bed of common earth in autumn; but to continue the different varieties distinct, they must be increased by budding, grafting, or laying, as in the other sorts.

The proper season for planting all the sorts of these trees is any time, in open weather, from November until March. And trees of all the varieties will mostly succeed in any common soil, and open exposure; but some of the best sorts should always be put for walls and espaliers, those for walls generally having an east or west aspect, or even a south wall for some of the choicest sorts; and a few may also be planted against a north wall, to furnish late fruit: and those for espaliers may be planted round any of the open quarters, as also the standards.

The trees designed for walls and espaliers should be planted out fifteen or eighteen feet distance; though where the walls, &c. are rather low, eighteen or twenty feet distance may be requisite, in order that, in default of a proper height of walling, there may be more scope to train the branches horizontally. But when the trees thus planted are quite young, as only of one year's shoot from the grafting or budding, they should in March be headed down, as above, to four or five eyes, to force out lower horizontals in the ensuing summer; which, according as they advance in length, should be trained horizontally at full length all summer, unless it be necessary to forward a further supply of lower branches as fast as possible; in which case, the young shoots should be pinched off in May down to a few eyes, when each will throw out several lateral branches the same year, which should also be trained horizontally at full length during their summer's growth; and in the winter pruning, cutting out only any foreright and back shoots, training-in all the regular ones at full length; as the branches of these trees should be shortened only occasionally to procure wood to fill vacancies, as the branches always form fruit-spurs first towards their extreme parts, which would be destroyed by shortening: so that, after having shortened the first and second year's shoots occasionally, as above, and thereby procured a proper set of lower horizontals, to give the head its first form; the whole may then be trained in entire about four, five, or six inches asunder; and, accordingly as the trees shoot, every sum-

mer training in a necessary supply of the regular shoots to fill the wall, &c. at the same time retrenching superfluities, and irregular and very rank luxuriant growths, training the supply of regular wood still at full length at the above distances; by which the trees will soon cover a large space, and the same unshortened branches continue bearing many years. See PRUNING.

The necessity of this sort of training is obvious from all the sorts bearing principally upon spurs, half an inch or an inch long, arising from the sides of the branches, of from one or two to many years old, which if shortened would throw out a multiplicity of useless wood, and hardly any fruit-spurs.

All the sorts of wall and espalier trees of this sort should be pruned twice every year, as in summer and winter, in order to retrench the superfluities of each year, and all foreright and other irregular shoots, and bad wood, and to train in a necessary portion of young wood where wanted to fill vacancies, or to supply the place of decayed, worn-out, and other bad branches. See PRUNING.

The standard-trees should be trained as full standards and half-standards, budding or grafting the former six feet high, and the latter only three or four; both kinds being worked low in the stock, training the first shoots to those heights for stems, then suffering them to branch and form heads: these may be planted out at from twenty to thirty feet distance, letting their heads form naturally.

Mr. Forsyth advises, that in choosing the trees the same directions should be observed as given below for apricots. "Clean straight plants, with single stems, should be employed, as those with two never make handsome trees on walls or standards, and the border should be managed as directed for apricots; digging the holes the same width and depth, and loosening the bottom: then fill up the holes with fine fresh loam, or the mould that was used the preceding year for melon and cucumber beds; being careful to keep the mould a proper height above the border, and the roots of the trees as near the surface as possible, spreading them horizontally. When there are any tap-roots, they should always," he says, "be cut off, as should also the fine hairy roots, as they are liable to get mouldy and rot, and thereby bring on a putrefaction of the mould about the root of the tree. When the roots are not spread near the surface of the ground, it will," he says, "prevent the sun and air from penetrating to them; and the fruit, of course, will not have so fine a flavour." He further advises "that the stems of young plum-trees should never be cut when first planted, but be left

till the buds begin to break, when they may be headed down to five or more eyes, always observing to leave an odd one for the leading shoot; always cutting sloping towards the wall, and as near to an eye as possible. Thus managed, the shoots will," he says, "soon fill the wall with fine wood. When it is found that some of the shoots are too luxuriant, they may have the tops pinched off with the finger and thumb, as above, about the beginning of June in the first year after planting; by doing which plenty of wood may be obtained to fill the bottom of the wall." He adds, that "a great deal depends on the first and second year's management of the trees."

With respect to the distance from each other at which Plum-trees should be planted against a wall, "it depends," he says, "on the height of the wall. If the wall be ten feet high, which is the common height, they may be planted at eight yards distance from tree to tree; but if the wall be twelve feet high, or more, seven yards will be sufficient." For his part, he prefers a wall of ten or twelve feet, which will, he thinks, be found high enough, if the branches are trained horizontally; by which means the trees will, he thinks, be much more fruitful, and not grow so luxuriantly. He further adds, that "by training an upright shoot on the Plums, as directed for Pears, fine kind shoots may be gotten from the sides. The leading shoot should be shortened, leaving it from one to two feet long, according to its strength. If the leading shoot be very strong, it may," he thinks, "be topped twice in the summer, as for Pears, and at the same time repeating the same every year till the wall is filled to the top." He would always recommend, where it is convenient, to allot one wall for Plums and another for Cherries, as they always thrive best by themselves, or when distinct.

As there will be Plum-trees to spare, that were planted between Pear-trees, when they begin to meet, these should, he says, be planted against another wall, or as dwarf standards. Those intended for standards should, he says, be prepared in the following manner: The year before they are to be planted they should be cut in the side-shoots at different lengths, from one foot to three, according to the size of the trees; suffering them to grow rude all the summer, neither nailing in nor cutting the side and foreright shoots. And some time during the winter the ground round their roots should be opened, cutting in the strong ones (which will cause them to put forth fine young fibres); then filling in the earth. In the following autumn, or during the winter (the sooner the better), they should be transplanted out as Standards. And in transplanting of the

trees, especially large ones, he considers it to be of great consequence that they be placed in the same position (that is, having the same parts facing the same points of the compass) as formerly. If notice be taken when a tree is cut down, it will, he says, be found that three parts in four of the growth are on the north side. When it is intended to plant them against a wall, they should never be cut in the side-shoots, but only the roots; by this method the trees will, he says, bear fruit the first year after transplanting, and there will be a great saving of time and money. He has often transplanted old Plum-trees that have been headed down that have made very fine roots, which he has divided, and thereby obtained four or five trees from one, cutting them so as to form them into fine heads. "Some that were transplanted in 1798 were in full blossom in 1799, producing some fruit, and in 1800 bearing a full crop."

It is recommended further by the same author, that "the ground in the borders and quarters where fresh trees are to be planted should be well trenched, two spits deep at least, to give the roots room to run into the fresh-stirred ground." And he says that when trees are planted without stirring the mould they seldom thrive well.

He advises that "when Plum-trees are planted for standards in an orchard which is to be kept for grass, they should be in rows at the distance of twenty yards from each other. If in the kitchen-garden for standards, he would always recommend the planting of dwarfs." The tree may be trained up to have a stem of about three feet high, at the distance of seventeen yards. "If the garden is laid out with cross-walks, or foot-paths, about three feet wide, the borders should be made six feet broad, planting the trees in the middle of them. In the royal gardens at Kensington, which are very long and narrow, and where the winds are very hurtful, he has, he says, planted two rows of apple-trees, intermixed with other fruit-trees, alternately, one row on each side of the middle walk (which runs the whole length of the garden), at the distance of seventeen yards from each other. He has also made cross-walks of three feet broad at the distance of seventy yards, with borders on each side six feet wide, having two rows of trees in each border, about twelve or fourteen feet asunder. These dwarf-trees are very useful in breaking the force of high winds, and are at the same time of such a height that a man standing on the ground may gather the fruit. As Plum-trees may be planted in the same manner and for the same purpose as the above, he can have the quarters clear for crops for the kitchen, and a free air be admitted, which

VOL. II.

can never be had where espaliers are planted: Dwarf Standards can, he says, be kept to what size you please; they look much handsomer than espaliers, and produce a greater quantity of fruit."

In regard to the method of managing and restoring old decayed trees of this sort, he remarks that he has restored "some of them which were so far decayed as to have only from one to two or three inches of bark left; they are now completely filled up with sound wood, with large heads, which at four years' growth filled a wall sixteen feet high, and are at this time full of fine fruit; some of the stems are several inches in circumference, bearing treble the crops produced by young trees that have been planted three times as long as they have been headed down. Where the trunks are become hollow, he always cuts out all the loose rotten parts, and also examines the roots, cutting off what is rotten, injured, or decayed. This method should, he says, be pursued with all hollow and decayed trees; and, if properly executed, they may be so completely filled up, as scarcely to leave a mark behind, even where the wood is totally decayed. He has had shoots from trees of this sort which have been headed, that have grown upwards of seven feet long, and as large as a walking-stick, in one summer: this should never be suffered; but they should be pinched off with the finger and thumb, in the beginning of June, close to an eye or a bud, unless the wall be filled to the top; in which case they should never be cut while they continue to bear handsome fruit. Before they begin to cease from bearing, you must always, he says, begin with shortening every other shoot, leaving them only from six inches to a foot long, and nail them in till the second year, taking care to rub off the superfluous and strong foreright shoots; by that time they will begin to bear: then cut out the others that have done bearing: by this method you will, he thinks, keep the trees in a flourishing state. When the branches are thus managed, they will frequently throw out small duggs, or foreright shoots, about an inch or two long, which will flower next year. They should never, he says, be shortened till after the fruit is set and become about the size of a large pea; by that time the leaves will have covered the fruit, and be able to protect it from the inclemency of the weather. You may now shorten these shoots close to the fruit, which will leave them from one to two inches long. This method he has practised with great success for several years. By leaving these short foreright shoots, the fruit is, he says, protected till it is out of danger of being killed by the

frost, or stunted by the cold north and north-west winds that happen about the latter end of March and beginning of April. The cold chilling rain and snow, which are also very injurious to the fruit, will be thrown off by the branches standing out from the trees. He by no means likes to see great spurs standing out from the wall; for they are always sure to be injured by the frost and cold winds. When the shoots are left naked, he has often seen the plums turn yellow, and drop after they have grown to a considerable size, from their being exposed to the cold frosty winds and rain. They should therefore, he thinks, in cold and frosty weather, be covered in the same manner as Apricots. Plums are, he remarks, more tender than any other sort of stone-fruit, owing to the flower-cup dropping sooner than that of peaches, nectarines, &c. And they are very liable to decay, after cutting off large limbs or branches, which always brings on the gum and canker, if it be left to Nature to perform the cure. He would, therefore, recommend the application of the Composition (in the same manner as directed for other sorts of fruit-trees) to every shoot where the knife touches, as soon as the trees are cut and nailed." And with the intention of having the fruit large and fine, care must be taken to thin it where it is too thick; but that must not be done too soon, lest it should be pinched by the cold. The fruit ought to be of the size of a small marble, and well sheltered by the leaves, before any attempt is made to do this." He advises never to pull off the leaves that shelter the fruit, till it is full-grown and begins to turn. See *AMYGDALUS*.

In conclusion it is also observed, that "he has taken up several old trees from the walls, when they have grown too near each other, and planted them out as standards, at the same time shortening their branches to form handsome heads, which are now full of fine fruit." These hints and directions are highly deserving of attention, as being the result of much practical experience.

Culture in the Apricot kind.—These trees are increased by budding them upon any kind of Plum-stocks, for which purpose they are raised from the stones of the fruit, sown in autumn in beds of light earth two inches deep; when they will come up the following spring, and in autumn or spring after be fit to plant out in nursery-rows; when in a year or two they will be fit to bud for dwarfs for walls, &c. but for half standards and full standards they must have three, four, or five years' growth, and be trained up with stems from three or four to six feet high; though sometimes the budding for

standards is performed low in the stock, and the first shoot trained up for a stem.

The operation of budding should be performed in August, being careful to procure shoots from which to take the buds from trees of the best sorts, performing the operation in the usual way. See *INOCULATION*.

The buds shoot in the following spring; at which time, before they begin to push, the stock should be headed down a little above the insertion of the bud; soon after which the buds will shoot and advance rapidly, and by autumn form a large shoot, and the trees are then proper for planting out for good, especially the dwarfs intended for wall-trees; or some may remain a year or two longer in the nursery, and be trained in a proper manner for planting against walls; and others for standards. But whether they remain in the nursery, or are planted out into the borders, the first shoot from the bud should in the March following be headed down to four or five eyes, to procure lower horizontal branches, as in the Plum.

When those intended for wall-trees are of one year's growth, with their first shoots or head entire, they are of a proper size for planting out finally where they are to remain. They may be planted out any time in open weather, from October until the beginning of March, choosing a south wall for the early and some other kinds, to come in forward; but as those exposed to the full south sun are apt to become soon mealy, it is proper to plant a principal supply against east and west walls.

Mr. Forsyth however thinks, "the best time for planting Apricots is in autumn, as soon as the leaf begins to fall. The person who goes to the nursery for the plants should, he says, make choice of those which have the strongest and cleanest stems; and if he can procure such as have been headed down, (to use the phrase of the nurserymen) of two or three years' growth, they will bear and fill the walls much sooner than those which have not been so treated. He should make choice of trees with one stem; or, if they have two, one of them should be cut off; for by planting those with two stems the middle of the tree is left naked, and, of course, one third of the wall remains uncovered." And though it is a practice with many to make choice of those with the smallest stems, he thinks they always make weaker shoots than the others.

These trees succeed in any common soil; they are usually planted in a range close along the wall, at eighteen feet distance, with their heads entire, which should be fastened either to the wall or to stout stakes, one to each tree, to pre-

serve them steady until spring, when they must have their first pruning, &c.

Mr. Forsyth however directs that, "if the borders wherein the trees are to be planted be new, they should be made two feet and a half or three feet deep, of good light fresh loam;" and that, "if the trees are to be planted in old borders, where the earth has been injured by the roots of the former trees, it will be necessary to take out the old mould at least three feet deep, and four feet wide, filling up the hole with fresh loam, taking care to plant the trees about eight inches higher than the level of the old border, to allow for the sinking of the earth, that they may not be too deep in the ground."

After being planted, if the trees are only one year old, with their first head from the bud entire, they should be headed down in the spring, to four or five eyes, to force out branches below; after which the trees should have water in dry weather, and the shoots from all the remaining eyes should in summer be nailed up regularly to the wall at their full length; and if any fore-right or back shoots come out, they should be rubbed off, being careful to continue the regular shoots to the wall all summer and the following winter; and in spring each shoot should be shortened to about eight, ten, or twelve inches, according to their strength, leaving the lowermost ones, on each side, rather the longest; this pruning short being still necessary in order to procure a further supply of lower branches, that every part of the wall may be occupied quite from the bottom; having particular attention to preserve nearly an equal number of branches arranging on each side of the tree, nailing them close to the wall horizontally, four, five, or six inches asunder. In the summer following, each horizontal branch will push out three or four, or more, new shoots, of which, if any rise fore-right and behind the branches, they should be rubbed off early in the season, nailing in all the regular side-shoots at full length during the summer, except it is necessary to pinch any particular shoot early to fill a vacancy. In the winter pruning, if there be any superfluities, or irregular growths left in summer, they should be cut out close, and all the regular-placed necessary shoots be shortened, though they should not now be pruned so short as in the two first years, only cutting each shoot according to its strength, from about eight or ten to fifteen or eighteen inches long: as the head of the tree is now tolerably well formed, therefore pruning only so as to obtain a further supply of wood, and a production of fruit; for as these trees bear princi-

pally upon the year-old wood, it is proper to train in a general supply of young shoots, of each year, in every part; the same shoots producing at the same time both a crop of fruit and a supply of wood for next year's bearing. The annual supply of wood must always, however, be shortened in the winter pruning; for if left entire it would produce only some shoots near the top, and leave the bottom naked, so as in a few years the whole tree would become very thin of bearing-wood below, and bear only a little towards the extreme parts of the branches. In the winter pruning, the shoots should always be shortened according to the strength of the tree and situation and strength of the respective shoots. And as these trees bear also upon short spurs, arising upon the two-years-old branches, it is proper to preserve them wherever they appear, only retrenching such as project considerably fore-right; leaving all those of one or two inches long, as the young shoots, of one year's growth, are the principal bearers: those produced one year bear fruit the next, and a general supply must be every year retained, and not shortened in summer, which would force out laterals from every eye, and spoil the shoots for next year's bearing; but in the winter pruning, a general shortening is necessary, and the whole tree should then be regularly nailed to the wall.

Mr. Forsyth says that, "when the trees are planted, they should by no means be headed down till the month of April or May, when they begin to throw out fresh shoots: strong trees should be cut a foot from the ground; and those that are weak, about half that length. But in backward seasons, they should not be headed down so early; never until the buds are fairly broken: always observing to cut sloping towards the wall, and as near to an eye as possible, that the young leading shoot may cover the cut; which operation should be again performed in the next March or April: the shoots that are then thrown out must be trained horizontally, to cover the wall: the number of these to be left ought to be from three to six on each side, according to the strength of the main shoot; taking care to rub off with the finger and thumb the fore-right shoots all over the tree, except a few which may be wanted to fill up the wall, near the body of it: and in the second year the horizontal shoots must be shortened in the same manner, according to their growth; and so on every year till the wall shall be completely covered from top to bottom." He adds that "it is a frequent practice with some gardeners, to head down the trees at the time of planting; which often proves fatal to them."

These trees must be pruned twice every year, as in summer and winter.

In the summer pruning, the irregularity of the numerous shoots should be reformed, beginning in May or early in June, and rubbing or cutting off close all fore-right and back shoots, and all superfluities or very rude growths; retaining, however, in every part, a full supply of the regular side-shoots, as succession-wood for the next year's bearing, training them in at full length, as above, to remain till the winter pruning; as it is of importance to leave more than a sufficiency of the well-placed shoots at this season, to have plenty in every part to choose from in the general winter pruning. See PRUNING.

In the winter pruning, a general reform should be made in all the branches and shoots, retrenching all worn-out and old naked branches ill-furnished with bearing-wood; at the same time selecting and retaining, in every part, the best shoots for next summer's bearing, cutting out close all the superfluous or unnecessary and ill-placed shoots, and reducing part of the former year's bearers and unfruitful old branches in every part of the tree, to make due room to train the necessary supply of young wood at proper distances; being careful, in retrenching the old wood occasionally, to prune it down either to a young shoot, or to some convenient branch it supports, which is furnished with one or more such shoots, so as every branch may also terminate in a young shoot for its leader, cutting off all the small shoots arising from the sides of the main ones, and letting the general supply of young wood in every part be now shortened moderately, according to their strength: the smaller shoots may be cut to about eight or ten inches, the middling ones to twelve or fifteen, and the strong shoots to eighteen inches or two feet long, pruning them generally to a wood-bud, in order to obtain a shoot at the end for a leader. All dead wood, cankered parts, decayed spurs, and stumps should be cut out; and as soon as one tree is pruned, let it be directly nailed, which should be performed with great regularity, training all the branches, &c. horizontally, as straight and close to the wall as possible, at equal distances. See PRUNING.

When these trees are of a strong vigorous growth, the shoots should be left thicker or more abundant than in moderate shooting trees, shortening them less in proportion, that by dividing the sap among many and a greater extent of branches, the luxuriancy may be restrained, as the more the strong young wood in a luxuriant tree is pruned, or the shoots short-

ened, the more vigorous the tree shoots, and produces little fruit. See AMYGDALUS.

The old trees should be well attended to in pruning, to continue them in a good fruitful state, by encouraging young wood in proper abundance; as by this care the trees not only more certainly produce crops, but the fruit generally ripens earlier, and has a peculiar richer vinous flavour. As these old trees are apt to run up naked below in the main branches, care should be taken when young wood advances in these parts, as well as in all vacant spaces, to preserve it so as to continue all the parts of the tree, from bottom upwards, regularly furnished with bearing wood.

In respect to old decayed trees, Mr. Forsyth says, "it has been the general practice to train wall-trees in the form of a fan, which occasions the sap to rise too freely to the top, leaving the lower part almost naked; so that scarcely one quarter of the wall is covered with bearing wood." He says that, "in that case, it will be necessary to cut down the whole of the tree, as near to the place where it was budded as possible, always cutting it at an eye or a joint: if there should be any young shoots on the lower part of the tree, it will be proper to leave them, training them horizontally, which will check the flow of the sap, and thereby render them much more fruitful." He adds that, "very frequently, when large branches have been cut off in a careless manner, and the wounds left to nature, the whole tree is infected with the gum and canker; which, if not checked, will in a short time totally ruin it: the best remedy in this case is, he thinks, carefully to pare off the cankered part of the bark with a draw-knife, or other convenient instrument. You will frequently find the white inner bark infected, which must also be cut away, till no appearance of infection remains; this may be easily known by the brown or black spots, like dots made with a pen, of which not one must be suffered to remain: all the branches so cut and pared should, he says, be immediately covered with the composition in a liquid state." And "as we sometimes see walls with all the trees infected, it will in that case be most prudent to cut every other tree, leaving the rest for a supply of fruit till those which are cut begin to bear; this will be in the second or third year: when trees are in a very bad condition, they should, he thinks, be cut in a partial manner, taking off the worst branches first, particularly those in the middle of the tree, always cutting as near to the graft as possible; or every other branch may at first be taken out, leaving the

rest to bear; by which means there will be a supply of fruit while the other parts of the tree are renovating: it should be remembered, however, that all the cankered bark must be cut off without loss of time; otherwise the new wood will be infected. Old trees thus headed down will, he says, sometimes throw out very strong and vigorous shoots, which it may be necessary to top, as it will cause them to throw out side-shoots, and soon fill up the wall with fine bearing wood; but they should never be suffered to have any fore-right spurs, except little dugs: the topping should be done in the beginning of June, which will cause the tree to produce fine bearing wood for the next year: those trees must be pruned in March following, shortening the shoots from fifteen to six inches, but according to their strength, always leaving the strongest shoots longest. And wherever the knife has been used, the Composition must, he says, be immediately applied."

It is also observed that, "after the fall of the leaf, it will be proper to unnaïl the young shoots, leaving only a few to prevent the tree from being broken by the wind. By this method they will be more exposed to the sun and air, which will ripen and harden the wood much more speedily than if they be left nailed." He adds that "he has a great dislike to autumnal pruning of fruit-trees, of all kinds of stone-fruit in particular; for by pruning at that season you seldom fail to bring on the canker: and no fruit-trees are more liable to this disease than the Apricot: the reason is obvious,—the great acidity in these trees, the exposure of the wounds, and the dormant state of the sap, predispose to mortification; whereas, in spring, when the sap is beginning to flow, and will follow the knife, the lips will quickly grow: if the branches are small, a fresh bark and fresh wood will in one season completely cover the wound; but if large, a time proportionate to their size will be occupied: this process, however, is manifestly much accelerated by the application of the composition, which excludes the air and wet from the air- and sap-vessels of the tree."

In regard to the standard-trees, they sometimes in favourable seasons bear plentifully, particularly the *Breda* and *Brussels Apricot*, either in half or full standards: the half standards are more out of the power of the winds and cold air.

These should be planted in a sheltered warm situation in the full sun, that they may have the greater chance of setting a good crop of fruit, and of ripening more effectually with a rich flavour: their culture is nearly the same as

that of other standard fruit-trees: they require but little pruning, only just to reduce or retrench any very irregular growth or out-growing rambler, or occasionally to regulate confused crowding branches, and to cut out decayed wood; all which should be performed generally in winter.

Covering and protecting the Blossom and young Fruit.—As trees of this kind planted against walls blossom very early, both blossom and young fruit are very liable to be injured by frosts and cutting blasts; it is therefore useful to afford occasional protection, in unfavourable seasons, to some of the forwardest and most valuable kinds, either with mats suspended over the trees, or twigs of evergreens stuck between the branches, beginning the covering as soon as the blossom begins to expand, and continuing it till the fruit is fairly set: the mats to be used only on nights and in bad weather, but the evergreens to remain constantly till all danger is past.

Mr. Forsyth remarks that, "in severe weather, they ought to be covered before the flowers begin to expand; for he has often seen the blossoms drop off before they opened: and he asserts that the best covering is old fish-nets, which should be put on three-fold; and if a few branches of dry fern are stuck in among the branches before the nets are put on, they will assist greatly in breaking the force of the high winds." The common practice of covering with mats in the night, and taking them off in the day, by frequently exposing the trees to the cutting winds, does, he thinks, more harm than good. And the covering with branches of spruce-fir and yew, by being too close, he supposes, encourages a blight, and causes the leaves of the trees to curl, and the shoots to break very weak; whereas the nets admit a free circulation of the air, and at the same time break the force of the wind: when it happens to rain or snow in the fore part of the night, and freeze towards the morning, the drops are, he says, found hanging in icicles on the meshes, while the tree is almost dry: when the shoots become pretty long, and the leaves expand to cover the fruit, it will be necessary, he says, to keep the net clear from the tree, by placing forked sticks, from six inches to a foot long, between it and the wall: this will prevent the shoots and leaves from growing through the net: the forked end of the sticks should rest against the meshes of the net. See *AMYGDALUS*.

Thinning out the Fruit.—In some seasons these trees set many more fruit than can attain perfection; and as they sometimes are placed very close, or often in clusters, and sit close to

the branches without any yielding footstalks, as in cherries, &c. they, in their advancing growth, must impoverish and thrust one another off; thinning becomes necessary, which in wall-trees particularly should not be omitted, and it is also proper occasionally in standards in some degree. This business should be begun when about the size of large cherries, &c. and should be done with great regularity, leaving the largest, fairest, and best situated to grow to maturity, mostly all singly, or at least never more than two at the same eye, but most commonly single in the large kinds. The fruit thinned off makes excellent tarts, and should always be saved for that purpose, and for which use they may be thinned by degrees, both in wall-trees and standards; but not, in the former, so as to leave the superabundant fruit to grow large in any considerable degree, nor in great quantity, to rob the continuing crop of its proper nourishment: for this use they should always be gathered before they stone, or harden in the heart or middle.

Forcing of Apricots.—In this method the fruit is obtained much more early than in the natural way, and is effected by having the trees in hot-houses, or on hot-walls, or in bark hot-beds.

The proper trees for this purpose are the dwarfs, trained as wall- or espalier-trees, but sometimes as small low standards: they are mostly trained in the full ground till advanced to some degree of bearing, and then planted in the borders of the forcing-house and hot-wall, and trained in the manner of wall-trees, to a light open treillis: some also, as small dwarf standards, placed forward in the former, or occasionally in pots, and introduced in the same situation; in all of which, the trees, being well fresh-footed in their places, are forced at the proper season by means either of fire-heat, or bark-bed, or sometimes both occasionally in forcing-houses, but in hot-walls mostly by the former: the forcing-houses and hot-walls have mostly flues for fire-heat, and sometimes the former have a pit for a bark-bed; but where this is not the case, the whole bottom space is formed of good earth, and the trees planted in are generally in assemblage with peaches, nectarines, plums, &c. as the same degree of heat is suitable to the whole.

The proper season to begin the work of forcing is principally in January, or early in the following month; when, or rather a little time before, the glasses are shut close; and at the proper time the fires made in the furnace moderately every evening and morning, to heat the flues in a proper degree, to afford a moderate

regular heat, to warm the internal air to a proper degree, which forwards the trees to early blossoming and fruiting; having fresh air moderately admitted in fine days, and more freely when there is a warm sun; being sometimes watered both in the earth, and over the branches after the blossom is past, and the fruit fairly set. See FORCING-FRAMES, &c.

Culture in the Cherry kind.—These are all increased by grafting, and budding them upon stocks of any of the cherry kind, raised from the stones of the fruit of any of the sorts; but for having larger-growing trees, for standards, walls, and espaliers, the most general stocks used are the Wild Black and Red Cherry, raised from the stones of the fruit: they, however, grow upon any sort of these stocks, and likewise take upon Plums, though these stocks are not proper for general use: they are also capable of growing upon laurel-stocks; which, however, is only practised for curiosity, suffering a small part of the stock to grow up to show the singularity of the two sorts growing upon the same root. All the varieties likewise take upon the Bird-Cherry stocks; but this should only be practised when it is required to dwarf any of them as much as possible; which in this way are proper to train for small dwarf trees, either to plant in pots, or in the open borders, and in pots for forcing, or to plant in the borders of a forcing-frame. See FORCING-FRAMES.

But, for general use, stocks either of any of the Common Cherry varieties; or, to have larger trees, the Wild Cherry-stocks, should be used, as being the freest shooters and of longest duration; though, in raising the stocks, it is from the stones of the fruit, which should be sown in autumn in beds of light earth, covering them near two inches deep: they come up in the spring, and in the autumn or spring following, if the plants are strong, plant them out in nursery-rows two feet and half asunder, to remain for grafting, &c. which, when about the size of a large goose-quill to that of a person's little finger, or little more, they are fit to work for dwarf trees; but for standards, they must have at least four years' growth, as they must be grafted at five or six feet height. And to have trees of more moderate growth either for walls, small standards, or dwarfs, the Morello and small May Cherry stocks may be proper.

The grafting and budding of all the sorts is performed in the usual way, though the former is most proper for general practice, as they are not so liable to gum in the grafted part as in that of the budded trees. Though both methods

may be occasionally used, and may be practised as the stocks occur in proper growth, &c. whip-grafting is the most proper in the most part, in this method of raising them: the budding is performed in the common way: the grafting should be done in the spring, as February and March, and the budding in summer, as June or July: the dwarfs should be grafted or budded near the ground, and the half and full standards from three to six feet high: the grafted trees shoot the same year, and the budded ones the spring following.

When the first shoots from the graft or bud are a year old, those of the dwarf sorts for walls, &c. must be shortened down in March or beginning of April, to five, six, or eight inches long, according to their strength; to procure lateral shoots to form the head, and the standards may be shortened or left entire as the case requires: when wanted to form a spreading head, the first shoots should be shortened to force out lower branches; after this, the branches of the dwarfs and standards remain mostly at their full length; and while the trees continue in the nursery, those designed for walls, &c. should be trained to stakes, in a proper position, occasionally pinching or pruning young shoots of the year early in summer, down to a few eyes or buds where necessary, in order to procure a production of lateral branches the same season, to train in for a further supply of young wood, to increase the expansion of the branches as soon as possible to continue entire.

When the trees have from one or two to five or six years' growth they are proper for being finally planted out; though, if planted when their heads are not more than two or three years old, they succeed much better than larger trees. Mr. Forsyth advises the same attention in choosing these trees, as for apricots, peaches, and nectarines, and that they should be headed down the first year.

The season for planting them out is any time in open weather, from the end of October or beginning of November till March.

The wall and espalier trees should be planted eighteen or twenty feet distant; and where the walls are tolerably high, a half or a full standard may be planted in the spaces between the dwarfs, that while these cover the bottom and middle, the standards may cover the upper part of the wall.

When those planted against walls or espaliers were planted when only one year old from the grafting, &c. with the first shoot from the graft or bud entire, they should be pruned short in March or beginning of April, to furnish lateral branches; but if they were headed in the nursery, and horizontal branches obtained, they

must not be shortened afterwards, except occasionally in particular shoots to fill a vacancy: as the fruit-spurs first rise towards the upper end of the branches, a general shortening would not only cut away the first fruitful parts, but force out a great deal of useless wood. The necessary branches, arising every year after the first heading down, should be trained horizontally at full length, five or six inches asunder; and where wood is wanted some adjacent young shoot may be pinched in May or early in June, or shortened in the spring following, when it will push forth two or three laterals; being careful to retrench all fore-right and other irregular-placed shoots, and continue training the regular branches still at full length at equal distances, till they have filled the proper space of walling or espalier.

In these trees the bearing-wood does not want renewing annually, the same branches continuing bearing several years, and only want renewing with young wood occasionally, as any branch becomes barren or an ill bearer, except in the Morello, which generally bears the most abundantly in the year-old young wood: a general successional supply of each year's shoots should therefore be retained for successional bearers.

The trees in all the sorts should be pruned twice every year; a summer pruning being given early in the season, to retrench all the superfluous shoots soon after they are produced, likewise all fore-right and other ill-placed shoots, and rank wood, as soon as possible; and to pinch shoots where wood is wanted, so as there may be as little pruning as possible upon the older wood, which is apt to gum by much cutting; retaining, however, a general moderate supply of the regular-placed shoots to choose from in the winter pruning, training the whole at full length: and in the winter pruning, examining the general branches, old and young, both in the former trained bearers, and the retained shoots of the preceding summer, retaining all the fruitful and regular placed former trained branches; and if, among these, any irregularity, disorderly or improper growths occur, the whole should be reformed by proper occasional pruning. In old trees, as well as others, it is proper to retrench any worn-out or declined naked branches, which are destitute of bearing-wood, or fruitful spurs, and to cut out all decayed wood; retaining a plentiful succession of last summer's young wood, in proper places, where necessary, to supply the place of any unserviceable old wood now retrenched; and at the same time cutting out all superfluous, or overabundant, and other unnecessary shoots reserved last summer, not now wanted, leaving only some well-placed ones, in any vacant spaces, or some in particular parts, to train in between

the main branches, to be advancing for bearers, ready to supply any deficiency; and generally a terminal shoot to the general branches in all parts where the allotted space admits of extending them in proper regularity: accordingly as each tree is thus pruned and regulated, the general branches and shoots should be trained in regularly, and nailed to the wall, &c. about three to four or five inches asunder, all at their full length, to the extent of their limited space.

Mr. Forsyth advises, in pruning these trees, never to shorten their shoots, as most of them produce the fruit at their extremities, the shortening, or cutting off of which very frequently occasions the death of the shoot, at least of a great part of it. The branches, therefore, should be trained at full length. He has often seen the whole tree killed by injudicious pruning. Wherever the knife is applied, it is sure to bring on the gum, and afterwards the canker; which will inevitably kill the tree, he says, if no remedy be applied to the wounds.

The Morello in particular, and the Small Early May Cherry, bear both on the young wood of last summer, the fruit blossom buds issuing immediately from the eyes of the shoots very abundantly, and upon small natural fruit-spurs arising on the two and three years' wood and continuing on the older branches; but generally bear the most plenteously on the young wood; and therefore it is necessary, both in the summer and winter pruning, to attend to this and retain a general supply of the young shoots of each year trained in plentifully in all parts of the tree in summer, of the most regular placed, as many as can be conveniently admitted with proper regularity: and in the winter-pruning, making a general selection of the best well placed shoots of last summer, to train in for successional bearers the ensuing season, cutting out the superabundant, with part of the naked former bearers occasionally to make room for the young supply, leaving a terminal one to each mother branch, and thus train in the general branches and shoots horizontally, about three or four inches asunder, all at their natural length.

The Standard Cherry-trees should be planted twenty-one feet distance at least; but if for a whole orchard, twenty-four feet, or eight yards distant every way, will be requisite. The first shoots having been previously shortened in the nursery, if thought necessary to promote lower branches to form the head, plant them now with their heads entire, except just reducing any irregular growth, and suffer them to branch every way, and shoot in length as fast as they are able, not shortening any, and all the branches will soon form numerous fruit-spurs.

Little pruning is required for Standard Cher-

ries, as too much use of the knife, in the larger wood particularly, causes them to gum and canker; all that is necessary is, occasionally to retrench any very irregular growing branch, and all decayed wood.

In respect to old trees Mr. Forsyth says, "he has headed down a great many Cherry-trees which were almost past bearing, and so eaten up with the gum and canker, that what few Cherries they bore upon old cankered spurs were not fit to be sent to the table;" and that "in the years 1790 and 1791 he cut, or headed down, fifty trees. The operation was performed in the months of April and May in each year. These trees made shoots from three to five feet the same summer, bore fine cherries the next year, and have continued to bear good crops ever since: to the above trees he applied the Composition. At the same time he cut down twelve trees in the same row, but did not apply the Composition; these twelve trees all died in the second and third years after. They now, he says, gather more cherries from one tree where the Composition was applied, than they did from the whole number formerly; being also much finer and larger fruit. When Cherry-trees are very old, and much injured by large limbs having been cut off (which will, he says, infallibly bring on the canker and gum, and, if no remedy be applied, in a short time kill the trees); or if there are great spurs left standing a foot perhaps from the wall; the best way to bring them to have fine heads, and to cover the wall, is to head them down as low as possible, taking care to leave some small shoots, if there are any; if not, leave a bud or two at the ends of some of the shoots. Sometimes you will have a great difficulty to find any buds. If that be the case, in the spring, before you mean to head the trees, make some incisions in the branches. This should be done on different branches, at the most convenient places for filling the wall with good wood. The size of the incisions should be from one to two inches, according to the largeness of the branches; observing to make them just above the joint where the buds should come out. If you cut just below a joint, the shoot will die as far as the next bud or joint; and of course injure the tree, if no remedy be applied." He adds that "the time for performing this operation is in March, April, or May. But this "method of making incisions is only recommended where there are no young shoots or buds, and when the tree is in the last stage of the canker. Where you have a few young shoots, or buds, he advises to cut down the head as near to them as you can, and to take great care to cut out the canker till you come to the sound bark. The canker makes its appearance in these trees in the same

manner as in peaches and nectarines, and may be easily discovered by an attentive observer. "If any gum remains, it must, he says, be cut or scraped off; the best time for doing which is when it is moistened with rain; you can then scrape it off easily without bruising the bark. This operation is very necessary; and if it be neglected the disease will increase rapidly." And wherever the bark or branches have been cut off, the edges should be rounded, and the Composition applied.

It is observed that the general way of pruning these trees has been to leave great spurs, which continue to increase till they stand upwards of a foot from the wall, and become as thick as a man's arm: but it must be observed, that cutting off from year to year the shoots that are produced from the spurs, increases the canker, till large protuberances, like wens, are formed on the branches, becoming very unsightly; and these occasion them to produce only small and ill-flavoured fruit at a great distance from each other. When this is the case, the method he pursues is, to head the trees down as before directed.

And if the young shoots are properly trained, they will, he says, produce fruit the following year; and in the second year produce more and finer fruit than a young tree that has been planted ten or twelve years.

The same writer remarks, that "it has been a general complaint, that Heart Cherries are bad bearers when trained up as wall-trees; but by pruning them as Duke Cherries, he has brought them to bear in the same manner; that is, he leaves a great many fore-right shoots in summer, tucking them in with some small rods run across under the adjoining branches, to keep them close to the wall, and prevent them from being broken by the wind, and from looking unsightly. He advises, "never to make use of the knife in summer, if it be possible to avoid it, as the shoots die from the place where they are cut, leaving ugly dead stulps, which will infallibly bring on the canker. These shoots may be cut in the spring to about a couple of eyes, as Duke Cherries, which will form a number of flower-buds."

Mr. Forsyth well observes, that "as Cherries are a very considerable article of traffic in the London markets, and the markets of most towns throughout the kingdom, employing such a great number of people during the summer season in gathering, carrying to market, and selling them, the raising of them is certainly worth any gentleman's while, especially as the trees may be rendered ornamental as well as profitable, by planting them in shrubberies, &c.

Vol. II.

Gentlemen of small fortunes, who are at a great expense with their gardens and plantations, may, he says, in a great measure reimburse themselves by selling their cherries and other fruit (for which there will be plenty of chapmen), and thus enjoy at an easy rate the pleasures of a rational and useful recreation." And he adds, that "in all parts of the country, there are persons employed in collecting fruit for the markets, and to hawk it about from place to place; and surely it is much better to sell it to them, than to let it rot on the ground, or be devoured by birds and insects."

It is advised, "when Cherry-trees begin to produce spurs, to cut out every other shoot to make the tree throw out fresh wood: when that comes into a bearing state, which will be in the following year, to cut out the old branches that remain; by that method you will be able to keep the trees in a constant state of bearing, taking the same method as before directed with the foreright shoots. And great care should, he says, be taken to rub off many of them in the month of May, leaving only such a number as you think will fill the tree. By so doing your trees will continue in a fine healthy state, and not be in the least weakened by bearing a plentiful crop of fruit. The reason is obvious: the great exhalation which would be occasioned by the sun and air in the common mode of pruning is prevented, by the Composition keeping in the sap which nourishes the branches and fruit."

He adds, that he "cut some trees, as directed above, more than twelve years ago, that are now in as good a state of bearing as they were in the third year after the operation, and likely to continue so for many years."

He states that "a row of Dwarf Cherry-trees that stood against an old paling, with an old thorn hedge at the back of it, (which every year so infected them with a blight, accompanied by an immense number of caterpillars and other insects, that even in a fine year they could not gather eight baskets from the whole row) became so fruitful after the hedge and paling were removed, that they gathered forty-two pounds a-day for six successive weeks, besides what the birds, wasps, and flies destroyed. He mentions the fact to stimulate market-gardeners and farmers, who have large orchards and gardens, to exert themselves in trying every method, however unimportant it may at first appear, to improve and render them more fruitful, and concludes, that the Duke and Heart Cherries from these trees were as fine as any that were produced from wall-trees. And, as they are much more productive, he has been induced

to take up many old renovated trees from the walls, and plant them out for dwarf standards, supplying their places with pears, plums, peaches, &c." And further he says, that "in all old gardens and orchards throughout the kingdom, and particularly Kent, whence the London markets are chiefly supplied with Cherries, the greater part of the old trees will hardly bear fruit sufficient to pay the expense of gathering it; but if the above method of pruning, &c., were practised, the owner would soon find his account in it, and be amply repaid for his trouble: the fruit would be much finer, and he would have five times the quantity that the trees produce in their present condition; the trees would be more sightly, and always keep in a flourishing and bearing state: but when old standard Cherry-trees become decayed and hollow, he would recommend heading them down, as directed for wall-trees and dwarfs, to scoop out all the rotten, loose, and decayed parts of the trunk, till you come to the solid wood, leaving the surface smooth; then use the Composition."

Forcing of Cherries.—This sort of tree may likewise be forced by artificial heat, in houses, so as to obtain fruit at an early season, as in April and beginning of May. And for this purpose the earliest Dukes and May Cherry are the proper sorts, but principally the former; trained both in standards, of four, five, or six feet stems, to elevate the heads near the top glasses of the forcing-house, which are generally pruned to a small compass for that purpose; and in dwarf standards, with short stems and low heads: both of which, for this use, should be such as are previously trained in the full ground, till the heads are of three, four, or five years' growth, or till they have commenced bearers in some tolerable degree. The forcing-houses for this use are of different constructions, according to circumstances, and the other purposes to which they are applied. They have proper flues for fire heat, and mostly internal borders of good earth, either in the back part for the taller trees, and in the front for lower; or sometimes, where no internal bark-pit is made, for bark-bed heat: the forcing being effected wholly by fire, the whole bottom space is entirely formed into a bed of earth of proper depth, and the trees planted in it in rows from the back to the front, in some regular gradation according to their height; sometimes with dwarfs planted between the taller standards, and towards the front; and occasionally with dwarf trees in pots.

In this sort of forcing, a very slight degree of fire-heat is sufficient; therefore when there are

back flues they need not be employed, only that in the front being used.

The author of the *Scotch Forcing Gardener* observes, that where "the situation is dry, the bottom a kindly sand, gravel, or clay, and the soil a sandy loam to the depth of two feet; the border will require no other preparation than being well enriched with stable dung, and if possible a little marle, which ought to be trenched and well mixed twice or thrice during the summer before planting. But, where it is wet, the bottom a cankering gravel or cold clay, and the soil either a poor sand, gravel, or stubborn clay, care must, he says, be taken to render them otherwise, by paving the border to the breadth of twelve or fourteen feet, running a drain in front to carry off the wet, and removing the bad, and bringing in good soil; so as to compose a rich sandy loam to the depth of thirty inches at the wall, and twenty-four in front, allowing three or four inches for settling. If a new building is erecting for Cherries, it is immaterial, he thinks, whether the building or border is completed first, (providing the latter has a sufficient time allowed for the mixing and incorporation of the soil) as the front wall and flue stand on pillars, whose foundations ought to be at least six inches deeper (if the border is not paved) than the soil."

He considers "about the first of January to be a good time for planting; although a month sooner or later at this season is of little consequence, as there must be no fire-heat applied the first year. Having provided the necessary number of healthy, well-rooted, maiden, or one-year-trained May Dukes; as experience, he says, shows that no other Cherry deserves a place in a forcing-house, let them be planted against the trellis at the distance of eight, nine, or ten feet, according as the length of the house will best divide; filling-in the pits with vegetable mould from decayed tree leaves, and settling all with a little water. Riders, with five or six feet boles, which have been trained two or three years against a wall, and have produced a crop or two, should be provided to fill the upper part of the trellis, where they will yield a few crops before the dwarfs require their removal. These will generally produce a few fruit the first, and be sure to produce a full crop the second year."

The surface of the border should, he says, be forked over once a year, and a little well rotted dung occasionally worked into it.

In respect to the trees, he observes, that "the dwarfs or principals being the only ones intended ultimately to fill the trellis, the riders being planted solely for the purpose of obtaining

a crop or two while those are making their wood and forming their fruit spurs, and, by being checked by their removal, may not be expected to put forth much young wood while they remain there, it will be unnecessary in pruning to thin them out much, only let them be dressed regularly to the trellis, and (where not absolutely requisite) divesting them of any shoots they may make, paying respect to their fruit-spurs only; as when they have served this purpose they will be of no further use."

He says, that "after planting, the dwarfs, if maiden trees, should be headed down to two or three eyes, in order to make them put forth vigorous shoots, to furnish the trellis from the bottom: and, if they have been one year in training, the bottom branches should be laid well down, and the rest dressed in a regular manner to the trellis, using strings of fresh matting to tie with; and be careful to allow sufficient room in the ties, as much mischief is done to fruit, especially Cherry-trees, (which are so apt to gum) if not allowed a sufficiency of room. He makes it a rule to allow every shoot as much room in the shred, or tie, as will at least admit another of the same size along with it."

As these trees are "apt to gum, and the branches decay, from the slightest injury, it would be imprudent to train them horizontally; in which case, the loss of a branch is supplied with much more difficulty than when trained in the fan manner." This last method he therefore recommends. And "when the tree has produced its shoots to the length of five or six inches, they should be gone over and thinned, so as to enable the operator to lay them in at about the distance of ten or twelve inches; pinching off any that are produced fore-right, and which are, from their appearance, not forming for fruit-spurs; and, as they advance, let them be neatly laid in, and divested of any laterals they may produce. If all has gone well, at the end of the first year they will, he says, have produced shoots from twelve to thirty inches long, which should then be shortened to about two-thirds of their length. In the second season they will shoot vigorously, and begin to form many fruit-spurs on the preceding year's wood, which must be encouraged, for the production of a few fruit the following year. The trees should be kept clear of all superfluous and lateral shoots, laying the leading ones at the distance of eight or nine inches; and, at the end of the season, shortening a few of the strongest alternately, so as to make them break their buds in the spring in a regular manner; as they will not require to be any more shortened.

And in the third season, they will, he says, produce a few fruit, make fine spurs and moderate shoots; which, as they advance to the riders, room should be given, by lepping off their branches, or thinning away their foliage, so as to afford a free circulation of air and admission of sun. In the fourth season, they will produce a full crop of fruit; and often make such a progress towards the riders, that their presence becomes unnecessary; in which case, it will, he says, be advisable to sacrifice whatever fruit, or appearance thereof, there may be on them, to the encouragement of the principals. After the trees have filled their spaces, and have begun to produce plentiful crops of fruit, they will make little or no wood; and will require no further care, on the score of training, than to supply the place of any branch that from accident may die out or be destroyed."

These trees, from their nature, bear very little artificial (especially fire) heat, on which account he would not advise the forcing of them too early, especially if there be no more than one compartment for their culture; since, in that case, there would not be a continued succession for the supply of the table, and furnishing a dessert, till they came in on the open walls. He considers the first or middle of February to be an eligible time for the commencement of the forcing; but, in a new planted house, the third year ought to arrive before fire heat is applied. Were it not for the sake of other articles that may be placed or planted in the Cherry-house, it would, he thinks, be better that the glasses were not put on the first season at all; but this is generally too great a sacrifice: however, if they are put on, a free circulation of fresh air, even in the night, ought to be encouraged. When in the third year after planting, the trees have made good progress, plenty of fruit-spurs, and a reasonable hope of success is entertained, the glasses should be put on about the middle of January, plenty of air being admitted through the day, shutting them up at night. On the first of February the fire may be lighted, which must, he says, be made so moderate, that, at eight at night, and eight in the morning, Fahrenheit's thermometer may not stand above 40°. In which condition it should be kept as near as possible till about the twentieth of the month; and then increased gradually to 45°: at which point endeavour to keep it till the fruit is fairly set. Afterwards increase the heat to 50°, but not more, till the stoning is over, and the fruit are begun their second swelling. Although, for the sake of the fruit, all danger is then past; yet, if too strong a fire heat is indulged in, it will, he says, have the tendency of

drawing the shoots too weak: and therefore he would not advise that the air of the house, at the fore-mentioned hours, should ever pass 60°.

With regard to the admission of air, he says, "the house ought to be uncovered all the first season after planting: but, if this is not the case; and if, from the nature of what other plants are placed therein, it is imprudent to leave a little air in the house in the night, it should be opened by sun-rise in the morning, having a large and free circulation all day, shutting it up at sun-set. However, when the month of May arrives, it ought, he thinks, to be entirely uncovered. In the second season, he advises, that the glasses be put on by the first of March, large portions of air being admitted, as directed above, and the glasses be removed by the first of August. From the commencement of the forcing, this article must, he says, be more particularly attended to; the first ten days after which, a very large share of air should be given, to prevent the buds from breaking too suddenly, and of consequence too weakly: besides, vegetation (in forcing) ought always to be brought on, as it were, by stealth: the juices flow more kindly; and the plant suffers the first impulse of reviving activity with more patience, than when hurried on in a violent manner. But, after the buds begin to appear turgid, a more moderate quantity may be admitted; still having respect to the temperature of the house, and the prevention of frosty winds from hurting the bloom." At all events, "advantage should be taken of sun-shine; which will allow a larger portion than at other times. Nevertheless, let no day pass (unless a severe frost) wherein less or more air is not admitted; and, in sun-shine, to the extent that the thermometer may not rise more than 10 degrees above the fire-heat medium. After the crop is all gathered, if consistent with the welfare of the other articles contained in the house, the glasses should be removed, and the trees exposed to the weather till the next season.

"When planted, the mould should be settled to the roots of the trees by a moderate watering; and if the house remain uncovered the first season, little attention (except in dry weather) will be required. Due attention should be paid the second year to keep the border in a moderately moist state, that the plants may grow freely; and when their growth is stopt for the season, withhold the water, that the wood may ripen perfectly before they are exposed to the weather. From the time the forcing is begun, plentiful waterings should be given to the border, until the bloom begins to open; and then in a moderate degree till the fruit is fairly

set. After which, again increase the quantity till the fruit begins to colour; and then diminish the quantity by degrees till you entirely withhold it, which ought to be done some time previous to the fruit's being ripe." It is also observed, that "washing with the hand-engine should commence with the day the fire is lighted; and, except from the time the bloom begins to appear till the fruit is fairly set, should be repeated thrice a week in the evening, and that with a considerable degree of force, till the fruit begins to ripen. And in the interval of washing, (viz. while in bloom, and till the fruit is set) a little water should be poured on the flue every evening when the fire is at the strongest, which causes a fine agreeable steam to arise in the house, greatly to the benefit of the flowers and foliage. Soft and tempered water should be used at all times, and on all occasions."

With respect to the insects that infest the Cherry House, they are, "the aphid, or green fly; the acarus, or red spider; the caterpillar, and the grub. The first, and least hurtful, is easily destroyed by a fumigation of tobacco. The second, by the process of washing with the engine, which is indispensably necessary to the health and vigour of the trees. Therefore, when they begin to make their appearance at any time, the water, in the ordinary course of washing, should be thrown against the trees with greater force, making a point of beginning at the contrary end of the house each time; whereby, if you happen to miss any part the one way, you may strike it the other. The caterpillar and grub have, he says, given him more trouble than the preceding, or indeed any species of insect whatever; and, after trying a variety of prescriptions, being at much trouble and expense, he can venture to assure the reader, and the public, he has at last discovered a cure", which is as follows:

"Take of soft soap, two pounds; flowers of sulphur, two pounds; leaf, or roll tobacco, one pound; nux vomica, two ounces; and oil of turpentine, a gill: boil them all together in eight gallons of soft or river water to six; and set the liquor aside for use. And any time in winter, at least a considerable time before the trees begin to vegetate, let them be all untied or unnailed the trellis or wall; brush every part of the branches and buds clean with a soft brush, such as is used for painting: make the liquor milk-warm; and, with a sponge, carefully anoint every part of the tree, trellis, &c. Dress the trees neatly to the trellis again; but use none of the old ties or shreds: and let this operation be repeated every winter. The first summer after

anointing, there may, he says, be a few appear, whose eggs have, by being concealed, escaped the action of the liquor, which must be picked off, to prevent their breeding; but, if any, there will be very few, as it is of the most penetrating nature." But this liquor must on no account, he says, be used in summer, as it instantly destroys the foliage. Fruit-trees of all kinds should be anointed with this liquor every year; as it is, he says, equally destructive of every insect and their eggs, which infest them.

In cultivating Dwarf trees, in pots or boxes, it is observed, that "where there is an extensive variety of forcing, and a green-house, or conservatory, Cherries may not only be produced at an early season, but in a long succession, by removing the pots or boxes from one house to another. When there are twenty or thirty trees, they should be divided into four or five equal parts, to make as many successions; and be placed in equal rotation: first, (in November or December) in the green-house, where they may remain till they are fairly set; then, in an early peach- or vine-house, till they begin to colour; and lastly, in the pine or dry stove, to come to maturity. And a very rich compost, such as is used for cucumbers or melons, should be made use of, watering them frequently with the drainings of a dung-dill. They should also be washed or watered frequently over head with a hand squirt or watering pan; and be placed in the most airy situations."

The Double-blossomed sort may likewise be increased by grafting or budding, as in the other varieties, upon any kind of Cherry-stocks, and be trained both as dwarfs, half and full standards, to effect the greater variety in plantations and other places.

And the Wild Cherry is easily raised from seed, as the stones of the fruit; and any variety which affords large and fine fruit may be continued by grafting, &c., in which way it will bear sooner, for which a quantity of stones should be provided in autumn, when the fruit is dead ripe, and be sown in beds of light earth an inch and a half deep, when they will come up in the spring, and after having one or two years' growth may be planted out in nursery-rows, with their tops entire, training them up for standards, with stems six feet high, then letting them branch out above every way, to form heads.

They may be planted out as standards in orchards or any open grounds for the fruit, and in ornamental plantations of forest-trees, where they have a good effect.

The Bird-Cherry sorts may also be increased

in the same manner, and likewise by layers, which will readily strike root, and be fit for planting out in one year. They will also grow well by cuttings planted in autumn.

And the last sort is capable of being raised by grafting, and sometimes by layers.

Culture in the Laurel kind.—These are readily increased by seed and cuttings: but as cuttings are the most expeditious mode, they are most commonly raised in that way.

In the first mode, the seeds should be sown in autumn, when ripe, in beds of light earth, near an inch deep, allowing them some protection in severe frosts in winter, either by hooping and matting the bed, or covering it with dry long litter; but suffering them to remain uncovered in mild weather. The plants come up in the spring, giving occasional waterings in dry weather; and in the autumn or spring following, when the season is settled, planting them out in nursery-rows to remain two or three years, or till wanted.

The cuttings should be procured in August or September, in moist weather, from the same year's shoots, cutting them off from about eight or ten to twelve or fifteen inches long, with about an inch of the old wood to the bottom of each, if possible, though this is not indispensably necessary: then strip off the leaves from the lower parts, and plant them in a shady border, in rows, twelve inches asunder, planting each cutting half or two-thirds into the ground, giving water in dry weather, when those planted in August will be rooted the same year; and all in the following summer, shooting at top, perhaps a foot long, by the autumn; at which time, or in the spring after, they may be planted or bedded out in wide nursery-rows, to acquire strength, till wanted. In either of these methods the trees may be trained either bushy or of a shrub-like growth, or trimmed up to a single stem for standards.

These plants delight in a light loamy soil, which is not too moist.

The proper season for planting them out is in the early autumn or spring, according to the soil.

They are highly ornamental in clumps and plantations, in lawns, parks, or out-grounds.

Hedges are sometimes formed of the common laurel for ornament; but where this is practised it should not be trimmed with garden-shears, which mangle and spoil the beauty of the large leaves: all necessary cutting should be performed with a knife, in order to preserve the leaves entire, so as to make a fine appearance.

PSIDIUM, a genus containing plants of the exotic tree kind.

It belongs to the class and order *Icosandria Monogynia*, and ranks in the natural order of *Hesperideæ*.

The characters are: that the calyx is a one-leaved perianth, bell-shaped, five-cleft, permanent: segments ovate: the corolla has five ovate petals, concave, spreading, inserted into the calyx: the stamina have numerous filaments, shorter than the corolla, inserted into the calyx: anthers small: the pistillum is a roundish germ, inferior: style awl-shaped, very long: stigma simple: the pericarpium is an oval berry, very large, crowned with the calyx, one- or many-celled; the seeds numerous, very small, and nestling.

The species cultivated are: 1. *P. pyriferum*, White Guava; 2. *P. pomiferum*, Red Guava.

The first, in its wild state, grows to the height of seven or eight, sometimes of twelve feet, but in the state of cultivation, where the soil is good, it equals a middle-sized apple-tree, the trunk being six feet in height, and a foot and half in circumference: the bark is smoothish, of a yellowish brown colour, with large ash-coloured spots: the wood very hard and tough, used for ox-yokes and the like purposes, and well adapted for fuel: the branches numerous, the young ones four-cornered: the leaves blunt, entire, smoothish, on short petioles, two or three inches long, opposite: the peduncles are solitary, short, supporting a white sweet-smelling flower: the fruit smooth, having a peculiar smell, yellow, sulphureous, or whitish on the outside, roundish or more oblong, the size of a hen's egg or bigger, according to the soil: the rind is a line or two in thickness, brittle and fleshy; pulp rather firm, full of bony seeds, flesh-coloured, sweet, aromatic and pleasant. It is a native both of the West and East Indies.

This fruit is eaten with avidity by the natives, and also sometimes preserved with sugar.

The second species has a pretty thick trunk, twenty feet in height, covered with a smooth bark, and dividing into many angular branches towards the top: the leaves are two inches and a half long, and one inch and a half broad in the middle, rounded at both ends, having a strong midrib and many veins running towards the sides, of a light green colour, opposite on very short foot-stalks: the peduncles are axillary, an inch and a half long: the petals are large and white; the fruit shaped like a pomegranate, crowned, when ripe having an agreeable odour. It is a native of the West and East Indies.

Culture.—These plants are increased by seeds, which must be procured from the countries where they grow naturally; and when these are brought over in the entire fruit, gathered full

ripe, they succeed with greater certainty: they should be sown in pots filled with rich kitchen-garden earth, plunging them into a hot-bed of tanners bark, giving them water from time to time, as the earth dries. When the plants come up, they must have free air admitted to them in proportion to the warmth of the season; and, when they have attained strength enough to be removed, be each planted out in a small pot, filled with the same sort of earth, and be plunged into a fresh hot-bed, shading them from the sun until they have taken new root, when they should have a large share of free air admitted to them every day in warm weather, to prevent their drawing up weak; they must also be frequently refreshed with water in summer.

When they have filled these small pots with their roots, they should be shaken out and their roots pared, putting them into larger pots filled with the same sort of earth, and replunged into the hot-bed, where they should remain till autumn, when they must be plunged into the tan-bed in the stove: during the winter they should have moderate warmth, and not too much water, and in summer have plenty of moisture, and in hot weather a great share of air.

They afford ornament among other stove plants.

PSORALEA, a genus comprising plants of the shrubby exotic kind for the greenhouse and stove.

It belongs to the class and order *Diadelphia Decandria*, and ranks in the natural order of *Papilionaceæ* or *Leguminosæ*.

The characters are: that the calyx is a one-leaved perianthium, dotted with tubercles, five-cleft: segments acute, equal, permanent; the lowest double the length of the others: the corolla papilionaceous, five-petalled: standard roundish, emarginate, rising: wings crescent-shaped, blunt, small: keel two-petalled, crescent-shaped, blunt: the stamina have diadelphous filaments, (one single and bristle-shaped, nine united), ascending: anthers roundish: the pistillum is a linear germ: style awl-shaped, ascending, the length of the stamens: stigma blunt: the pericarpium is a legume the length of the calyx, compressed, ascending, acuminate: the seed single, kidney-form.

The species cultivated are; 1. *P. pinnata*, Winged-leaved Psoralea; 2. *P. aculeata*, Prickly Psoralea; 3. *P. bracteata*, Oval-spiked Psoralea; 4. *P. hirta*, Hairy Psoralea; 5. *P. bituminosa*, Bituminous Psoralea; 6. *P. Americana*, American Psoralea; 7. *P. corylifolia*, Hazel-nut-leaved Psoralea; 8. *P. Dalea*, Annual Psoralea.

The first rises with a soft shrubby stalk, four or five feet high, dividing into several branches:

the leaves are of a deep green colour, composed of three or four pairs of very narrow leaflets, terminated by an odd one, standing upon short footstalks, and coming out without order on every side of the branches: the flowers sit very close to the branches, and are often in clusters: the standard, which is erect and reflexed at the top, is of a fine blue; the wings are pale, and the keel white. It flowers during a great part of the summer, and the seeds ripen in autumn. It grows naturally at the Cape.

The second species is a shrub with angular branches, and lateral solitary flowers without bractes. It is a native of the Cape, flowering in June and July.

The third has a shrubby stem, determinately branched, with round pubescent branches: the leaves sessile: leaflets even, dotted, pointed at the end with a patulous spine: stipules chaffy, lanceolate, acuminate, ciliate: the spikes terminating, solitary, sub-villose, peduncled: the flowers separated by ovate-acuminate ciliate bractes, almost the length of the flowers; the corolla violet-coloured, with a white keel having a violet spot in front. It is a native of the Cape, flowering in June and July.

The fourth species is a shrub, with rough-haired rigid branches: the leaves petioled: leaflets sub-petioled, sub-pubescent: the flowers at the ends of the branches: calyces pubescent: corollas violet-coloured. It is a native of the Cape, continuing in flower most part of the summer.

The fifth has a perennial root, but the stalk not of long duration, seldom lasting more than two years: it rises about two feet high, sending out two or three slender branches: the leaflets about two inches long, and one inch and a quarter broad, on long foot-stalks: the leaves, if headed, emit a strong scent of bitumen: the heads of flowers are on axillary peduncles seven or eight inches long, and blueish, smelling like black currants. It is a native of Italy, Sicily &c., flowering most part of the summer.

The sixth species has diffused, herbaceous stems, with glandular dots scattered over them: the leaflets roundish, very blunt, obsoletely toothed or angular, sprinkled with glandular dots; the middle one larger and petioled: the spikes axillary, oblong, on peduncles the length of the leaves. It is a native of Madeira, flowering late.

The seventh is an annual plant: the stalks rise two feet high, and have at each joint one leaf about two inches long, and an inch and a half broad, having one strong midrib, from which come out several veins, that run towards the top of the leaf: the flowers are produced on long slender axillary peduncles, collected into

small round heads, and are of a pale flesh-colour. It grows naturally in India, and flowers in July in this climate.

The eighth species is also an annual plant, with a very branching herbaceous stalk, rising a foot and half high, spreading wide on every side: the leaves are composed of five or six pairs of narrow wedge-shaped leaflets, terminated by an odd one: the flowers are collected in close oblong spikes at the ends of the branches, are small, and of a light blue colour. It is a native of Vera Cruz.

Culture.—These plants are increased by sowing the seeds in the early spring months, on a moderate hot-bed, or in pots, plunging them in it. When the plants have attained three or four inches in growth, they should be planted out into small pots separately, gradually hardening them to the open air, so as to be placed out in it in the beginning of the summer. They are likewise capable of being increased by planting cuttings of the young shoots in the summer months, in pots filled with light earth, plunging them in a moderate hot-bed and covering them close with glasses, watering and shading them well till they have stricken root.

They afford variety among other potted greenhouse plants.

PSEUDO ACACIA. See ROBINIA.

PSEUDO ACORUS. See IRIS.

PSEUDO ASPHODELUS. See ANTHERICUM.

PSEUDO CAPSICUM. See SOLANUM.

PSEUDO DIGITALIS. See DRACOCEPHALUM.

PTELEA, a genus containing a plant of the shrubby kind.

It belongs to the class and order *Tetrandria Monogynia*, or *Dioecia Tetrandria*, and ranks in the natural order of *Terebinthaceæ*.

The characters are: that in the male, the calyx is a four-parted perianthium, acute, small, deciduous: the corolla has four petals, oblong, concave, spreading, larger than the calyx, coriaceous: the stamina have four awl-shaped filaments, erect, curved in at the top, flattish and villose at the base, almost the length of the corolla: anthers roundish: the pistillum is an ovate germ, small, abortive: style very short, bifid at the top: stigmas obsolete: female; the calyx and corolla as in the male: the stamina filaments, as in the male, much shorter than the corolla: anthers roundish, barren: the pistillum is an ovate germ, compressed, biggish: style short, compressed: stigmas two, bluntish, diverging: the pericarpium is a roundish drupe, large, juiceless, compressed, membranaceous-winged, two-celled; the seeds solitary, oblong, attenuated upwards.

The species is *P. trifoliata*, Three-leaved Ptelea, or Shrubby Trefoil.

It rises with an upright woody stem ten or twelve feet high, dividing upwards into many branches, covered with a smooth grayish bark, garnished with trifoliate leaves standing upon long foot-stalks: the leaflets are ovate or ovate-lanceolate, smooth, and of a bright green on their upper side, but pale on their under; these come out late in the spring, soon after which the bunches of flower-buds appear, which is generally in the beginning of June, the leaves being then but small, and afterwards increase in size, but are not fully grown till the flowers decay: the flowers are produced in large bunches at the end of the branches; are of an herbaceous white colour, composed of four or five short petals, ending in acute points; fastened at their base to a short calyx, cut into four segments almost to the bottom. It grows naturally in North America.

There is a variety with five leaves.

Culture.—This plant may be increased by seeds, cuttings and layers.

The seeds should be sown in the early spring months, as March, in pots filled with light rich mould, plunging them in a moderate hot-bed to bring up the plants, giving them occasional waterings during the summer season, and protecting them during the winter from severe frost, planting them out in the following spring in nursery-rows, to get strong for being finally planted out.

The cuttings should be made from the young shoots, and planted in pots filled with light earth in March, plunging them in a hot-bed to strike them, but they should not have much heat, due shade being given. They readily strike root, and may be planted out in the following autumn.

The layers may be laid down in the autumn, choosing the young shoots for the purpose, giving them a slit underneath, and then placing them in the soil. They are mostly rooted in the course of a twelvemonth.

These plants are proper for shrubberies and other places in pleasure-grounds, where they have a very ornamental effect.

PUDDING-GRASS. See *MENTHA PULEGIUM*.

PULMONARIA, a genus furnishing plants of the hardy perennial fibrous-rooted kind.

It belongs to the class and order *Pentandria Monogynia*, and ranks in the natural order of *Asperifoliae*.

The characters are: that the calyx is a one-leaved perianthium, five-toothed, prismatic-pentagonal, permanent: the corolla one-petaled, funnel-form: tube cylindrical, the length of

the calyx: border half-five-cleft, blunt, from upright-spreading: throat pervious: the stamina have five filaments, in the throat, very short: anthers erect, converging: the pistillum has four germs: style filiform, shorter than the calyx: stigma blunt, emarginate: there is no pericarpium: calyx unchanged, fostering the seeds at bottom: the seeds four, roundish, blunt.

The species cultivated are: 1. *P. officinalis*, Common Lungwort; 2. *P. angustifolia*, Narrow-leaved Lungwort; 3. *P. Virginica*, Virginian Lungwort.

The first has a perennial fibrous root: the lower leaves rough, about six inches long, and two inches and a half broad, of a dark green on their upper side, marked with many broad whitish spots, but pale and unspotted on their under side: the stalks almost a foot high, having several smaller leaves on them standing alternately: the flowers are produced in small bunches at the top of the stalks, of different colours. It is a native of Europe, flowering from March to May.

The second species has leaves much narrower than those of the first sort, and covered with soft hairs, not spotted: the stalks rise a foot high, and have narrow leaves on them, of the same shape with those below, but smaller, and almost embracing: the flowers are produced in bunches on the top of the stalks, of a beautiful blue colour. It is a native of Sweden.

It varies with white flowers.

The third has a perennial, thick, fleshy root, sending out many small fibres: the stalks a foot and half high, dividing at the top into several short branches: the leaves near the root four or five inches long, two inches and a half broad, smooth, of a light green, on short footstalks; those upon the stem diminish in their size upwards, are of the same shape, and sessile. Every small branch at the top of the stalk is terminated by a cluster of flowers, each standing upon a separate short peduncle. The most common colour of these flowers is blue; but there are some purple, others red, and some white. They appear in April, and if they have a shady situation continue in beauty great part of May. It grows upon mountains in most parts of North America.

Culture.—These plants are increased by seeds, and parting the roots.

The seeds should be sown in the spring, in a bed or border of common earth, raking them in. They soon come up, and in the latter end of the summer they should be put out, either where they are to remain, or in nursery-beds, till October, when they should be planted out finally.

The roots should be parted in the autumn, as about August or September, but the sooner

P U N

after they have done flowering, the better. They should not be divided too small, and be planted directly; when they flower strong in the following spring. They afford ornament in shady situations.

PUMPKIN or **PUMPKIN**. See **CUCURBITA**.

PUNICA, a genus containing plants of the tree and shrub kinds.

It belongs to the class and order *Icosandria Monogynia*, and ranks in the natural order of *Pomaceæ*.

The characters are: that the calyx is a one-leaved, bell-shaped, five-cleft perianthium, acute, coloured, permanent; the corolla has five roundish petals, from upright spreading, inserted into the calyx: the stamens have numerous capillary filaments, shorter than the calyx, and inserted into it: anthers somewhat oblong: the pistillum is an inferior germ: style simple, the length of the stamens: stigma headed: the pericarpium is a sub-globular pome, large, crowned with the calyx, divided into two chambers by a transverse partition, the upper having about nine, the lower about three cells: partitions membranaceous: the seeds very many, angular, succulent: receptacle fleshy, scrobicular, dividing each cell of the pericarp two ways.

The species are: 1. *P. granatum*, Common Pomegranate Tree; 2. *P. nana*, Dwarf Pomegranate Tree.

The first is a tree which rises with a woody stem eighteen or twenty feet high, sending out branches the whole length, which likewise put out many slender twigs, rendering it very thick and bushy, some of which are armed with sharp thorns: the leaves are narrow spear-shaped, about three inches long, and half an inch broad in the middle, drawing to a point at each end; are of a light lucid green, and stand opposite: the flowers come out at the ends of the branches, singly or three and four together; frequently one of the largest terminates the branch, and immediately under that are two or three smaller buds, which continue a succession of flowers for some months. The fruit is a pome berry, covered with a hard coriaceous rind including a pulp. It is a native of Spain, Portugal, &c. In the West Indies, where it is supposed to have been introduced from Europe, the fruit is larger and better flavoured.

There are several varieties: as the Large Double-flowered, and the Striped-flowered.

The second species seldom rises more than five or six feet high: the flowers are much smaller than those of the common sort; the leaves are shorter and narrower; the fruit is not larger than a nutmeg, and has little flavour: but it may be kept within compass; and in the West Indies, where it is a native, and is planted

Vol. II.

P Y R

for hedges, it continues flowering great part of the year.

Culture.—The first sort and varieties are readily increased by layers; which should be laid in autumn, choosing the young branches for the purpose, giving a little slit underneath at a bud, and laying them in the usual way, giving occasional waterings in summer; and by the following autumn they will be well rooted, and fit to be planted in nursery-rows for two or three years, to get strength, and then planted where they are to remain.

Those of the common sort and varieties may be trained as half or full standards, or as dwarfs; but those designed for walls should be managed as directed for peaches, &c.

This sort may be planted against warm walls, and be pruned and trained as other fruit-trees.

Of this sort, the double-flowering kind is much more esteemed than the other in this country for the sake of its large, fine, double flowers, which are of a most beautiful scarlet colour; and, if the trees are supplied with due nourishment, continue to produce flowers for two months successively; which renders it one of the most valuable flowering trees. This sort may be rendered more productive of flowers by grafting it upon stocks of the single kind, which check the luxuriance of the trees, and cause them to produce flowers upon almost every shoot.

The second sort may be raised also by layers, as the former, but must be planted in pots filled with rich earth, and preserved in a greenhouse. In the summer, when the flowers begin to appear, if the plants are exposed to the open air, the buds will fall off without opening; they should therefore be placed in an airy glass case, and a large share of air should be given them every day in warm weather. By this treatment the plants may be continued in flower upwards of three months, and make a fine appearance.

These are very ornamental trees for shrubberies and other places.

PURGING NUT. See **IATROPHA**.

PURPLE APPLE. See **ANNONA**.

PURSLANE. See **PORTULACA**.

PURSLANE TREE. See **PORTULACARIA**.

PYRUS, a genus containing plants of the fruit-tree kind.

It belongs to the class and order *Icosandria Pentagynia*, and ranks in the natural order of *Pomaceæ*.

The characters are: that the calyx is a one-leaved perianth, concave, five-cleft, permanent: segments spreading: the corolla has five petals, roundish, concave, large, inserted into the calyx: the stamens have twenty filaments, awl-shaped, shorter than the corolla, inserted into the calyx:

anthers simple: the pistillum is an inferior germ: styles five, filiform, the length of the stamens: stigmas simple: the pericarpium is a roundish pome, umbilicate, fleshy, with five membranaceous cells: the seeds some, oblong, blunt, acuminate at the base, convex on one side, flat on the other.

The species are: 1. *P. communis*, Common Pear-tree; 2. *P. Malus*, Common Apple-tree; 3. *P. spectabilis*, Chinese Apple-tree; 4. *P. prunifolia*, Siberian Crab-tree; 5. *P. coronaria*, Sweet-scented Crab-tree; 6. *P. Cydonia*, the Quince-tree.

The first grows to a lofty tree, with upright branches, the twigs or branchlets hanging down: the leaves are elliptical, obtuse, serrate; the younger ones clothed with a deciduous cotton underneath and along the edge: the stipules linear: the flowers in terminating villose corymbs of a snow white colour: the fruit is a pome. It is a native of Europe.

It is observed that "the Wild Pear, the mother of all the orchard and garden varieties, is thorny. The stipules are setaceous, white (or reddish), deciduous: the peduncles alternate; and the calyx clothed with a ferruginous wool."

There are numerous varieties; but those of most importance for cultivation are:

The Little Musk, which is often termed the Supreme. The fruit, when ripe, is of a yellow colour; the juice somewhat musky; and, when gathered before it be too ripe, is a good fruit. It becomes ripe about the latter end of July, but continues good only a very short time.

The Chio, or Little Bastard Musk, which is pretty much like the other, but smaller. The skin, when ripe, has a few streaks of red on the sun side.

The Green Chissel, or Hastings, which is a middle-sized fruit, that always remains green, and is full of juice when ripe. It becomes ripe in the beginning of August.

The Red Muscadelle, which is a large early pear, of great beauty; the skin is of a beautiful yellow striped with red, and the flesh has a rich flavour. It sometimes produces two crops in a year; the first about the end of July, and the second in September, or thereabouts.

The Little Muscat, which is a small pear, having the skin very thin, and of a yellowish colour when ripe. This fruit has a rich musky flavour, but does not keep long. It becomes ripe about the beginning of August.

The Lady's Thigh, which is here commonly called Jargonelle, is of a russet green colour from the sun, but towards it inclining to an iron colour; the flesh is breaking, and has a rich musky flavour. It becomes ripe about the middle of August.

The Windsor, which has a smooth skin, and when ripe is of a yellowish-green colour; the flesh is very soft, and, if permitted to hang but two or three days after it is ripe, grows mealy and is good for nothing. It becomes ripe about the latter end of August.

The Jargonelle, which is commonly called Cuisse Madame. According to Mr. Forsyth it is certainly the true French Jargonelle; and the pear which commonly goes by that name here is the real Cuisse Madame, or Lady's Thigh; it being very probable that the names have been changed in coming to this country. This pear is somewhat like the Windsor; the skin is smooth, and of a pale green colour. It is a plentiful bearer; but the flesh is apt to be mealy if it stands to be ripe, which is about the middle of August. It bears best on standards.

The Orange Musk, which is of a yellow colour spotted with black; the flesh is musky, but very apt to be dry. It ripens about the latter end of August.

The Great Blanquet, or Bagpipe of Anjou, which has a smooth skin of a pale-green colour; the flesh is soft, and full of juice of a rich flavour. It ripens about the middle of August.

The Little Blanquet, which is much less than the former; of a pale colour, and the flesh tender and full of a rich musky juice. It ripens about the latter end of August.

The Long-stalked Blanquet has a very smooth skin, white, and a little coloured towards the sun, and is full of a rich sugary juice. It becomes ripe at the latter end of August.

The Skinless or Early Russelet, which is of a reddish colour, the skin extremely thin, and the flesh melting and full of a rich sugary juice. It ripens in the latter end of August.

The Musk Robine, or Queen's Pear (also called the Amber Pear), which is small, and of a yellow colour when ripe; it has a rich musky flavour, and is a great bearer. It ripens about the latter end of August.

The Musk Drone, which has a skin of a yellow colour when ripe, and a rich musky taste; but is apt to grow mealy if left too long on the tree. It ripens about the beginning of September.

The Red Orange, which is of a greenish colour; but the side next the sun changes to a purple colour when ripe; the flesh is melting, and the juice sugary, with a little perfume. It ripens in the beginning of August.

The Cassolette, or Green Muscat, is a small greenish pear with some specks in the skin. It is full of a rich perfumed juice, and ripens in the latter end of September.

The Great Onion, Brown Admired, or King of Summer, which is of a brownish colour next

the sun, and becomes ripe in the beginning of September.

The Musk Orange, in which the skin is green, and the flesh melting. It ripens in the beginning of September.

The Avocat, or August Muscat, which has a smooth skin of a whitish yellow colour; the juice is richly sugared and perfumed, and it is esteemed one of the best Summer Pears yet known. It is a great bearer, and becomes ripe in the beginning of September.

The Rose, or Thorny Rose, which is shaped like the Great Onion Pear, but much larger, of a yellowish-green colour, but a little inclining to red next the sun. The flesh is breaking, and the juice musky. It becomes ripe in the beginning of September.

The Poire du Puchet, which has the flesh soft and tender, and the juice sugary. It ripens in the beginning of September.

The Perfumed Pear, which is of a deep red colour spotted with brown; the flesh melting, but dry, and has a perfumed flavour. It ripens in the beginning of September.

The Salviati, which is red and yellow next the sun, but whitish on the other side; the flesh is tender, and the juice sugary and perfumed. It ripens about the middle of September.

The Rose Water, which has the skin rough, and of a brown colour, the juice very sweet, tasting like rose-water. It ripens in the latter end of September.

The Russet, in which the flesh is soft and tender, and the juice agreeably perfumed. It ripens in the latter end of September.

The Great Mouthwater, which has the flesh melting and full of juice. It ripens about the latter end of September.

The Prince's Pear, which has a highly-flavoured juice, and is a great bearer, ripening about the latter end of September.

The Summer Bergamot, which is sometimes called Hamden's Bergamot. The flesh is melting, and the juice highly perfumed. It ripens about the latter end of September.

The Autumn Bergamot, which is smaller than the former; the flesh is melting, and the juice highly perfumed. It is a great bearer, and ripens in the beginning of October.

The Summer Bonchrétien, which is very full of juice, and is of a rich perfumed flavour. It ripens about the middle of September.

The Beurré Rouge, (the Red Butter Pear,) which has the flesh very melting and full of a rich sugary juice. It ripens in the beginning of October, and, when first gathered from the tree, is one of the very best sort of pears.

The Dean's Pear, which has the flesh melting

and full of juice, which is very cold. It is a great bearer, and ripens in the beginning of October.

The Swiss Bergamot has a melting flesh, and is full of juice. It ripens in the beginning of October.

The Long Green, in which the flesh is melting and full of juice. It ripens in the latter end of October. It is, by some, reckoned the same with the Mouthwater.

The White and Gray Monsieur John, which are the same; the difference of their colour proceeding from the different soils and situations wherein they grow, or the stocks on which they are grafted. If this pear be rightly managed, there are not many sorts in the same season to be compared with it. The flesh is breaking, and full of a rich sugared juice. It ripens in the latter end of October, or beginning of November.

The Flowered Muscat, which is an excellent pear; the flesh is very tender, and of a delicate flavour. It ripens in November.

The Vine Pear, which is of a dark red colour; the flesh very melting, and full of a clammy juice. It comes into eating in November.

The Rousseline Pear, which is of a deep red colour, with spots of gray; the flesh is very tender and delicate, and the juice very sweet, with an agreeable perfume. It ripens about the latter end of October, but does not keep.

The Knave's Pear, which has the flesh fine and tender, and the juice very much sugared. It ripens in the latter end of October.

The Marquis Pear is a pear which, when it does not change yellow in ripening, is seldom good; but if it does, the flesh will be tender, delicate, and very full of juice, which is sugared. It comes into eating in November.

The Crasane Pear, which has the flesh extremely tender and buttery, and full of a rich sugared juice. It is the very best pear of the season, and comes into eating about the latter end of December.

The Lansac, or Dauphine Pear, which has the flesh yellow, tender, and melting; the juice is sugared, and a little perfumed. It is in eating the beginning of December.

The Martin Sec (the Dry Martin), which is almost like the Russet in shape and colour; the flesh is breaking and fine; and the juice sugared, with a little perfume. It is in eating about the beginning of December.

The Amadot, which is rather dry, but highly-flavoured: it is in eating about the middle of December.

The Little Lard Pear, which is extremely fine; the flesh melting; the juice much sugared, and has an agreeable musky flavour. It is in eating the latter end of December, and is esteemed one of the best fruits in that season.

The *Louishon* (the *Good Lewis*), which has the flesh extremely tender, and full of a very sweet juice. It is in eating about the middle of December.

The *Colmar Pear*, which is very tender, and the juice greatly sugared. It is in eating about the beginning of January, and is esteemed an excellent fruit.

The *L'Eschasserie*, which has the flesh melting and buttery; the juice is sugary, with a little perfume. It is in eating about the first of January. It bears best on standards.

The *Virgouleuse Pear*, which is esteemed by some as one of the best fruits of the season; the flesh is melting, and full of a rich juice. It is in eating about the first of January. In dry and cold seasons it is very apt to crack, which greatly diminishes its value.

The *Ambrette*, which is esteemed a very good pear; the flesh is quite melting, and full of sweet perfumed juice. It comes into eating about the beginning of January.

The *Epine d'Hyver* (the *Winter Thorn Pear*), which has a very tender buttery pulp, of an agreeable taste, with a sweet juice highly perfumed. It is in eating about the latter end of December.

The *St. Germain Pear*, which is a fine fruit and keeps long; the flesh is melting, and very full of juice, which in a dry season, or if planted on a warm dry soil, is very sweet. It is in eating from December till February. Mr. Forsyth remarks, that it is "an excellent bearer, when planted as a dwarf standard, and comes in succession after the same sort of pears on wall-trees are over."

The *St. Austin*, which is pretty full of juice, and which is often a little sharp; the flesh is tender, but not buttery. It is in eating the latter end of December, and continues good two months, or longer.

The *Spanish Bonchrétien*, which is a large fine pear; the flesh is breaking, and the juice sweet. It is in eating in January.

The *Wilding of Cassoy*, which is also called the *Small Winter Butter Pear*, is a small fruit; the flesh is melting, and the juice very rich: it is an excellent bearer on standards. It is in eating in January.

The *Martin Sire*, or the *Lord Martin*, which is a good fruit; the flesh is breaking and full of juice, which is very sweet and a little perfumed. It is in eating in January.

The *Winter Russelet*, which has the flesh buttery and melting, and generally full of a sweet juice. It is in eating in the latter end of January.

The *Franc Real*, or the *Golden End of Winter*, which is only esteemed for baking.

The *Brown Beurré*, which is of a reddish-

brown colour on the side next the sun, and yellowish on the other side. The flesh is melting, and full of a rich juice. It ripens in October, and is esteemed an excellent pear.

The *Holland Bergamot*, *Amoselle*, or *Lord Cheney's*, which is a very good pear; the flesh is half buttery and tender, and the juice is highly flavoured. It keeps from the end of January till April.

The *German Muscat*, which is an excellent pear; it is buttery and tender, and the juice is highly flavoured. It is in eating from February till April or May.

The *Pear of Naples*, or *Easter St. Germain*, which is half-breaking; the juice is sweet, and a little vinous. It is in eating in March.

The *Winter Bonchrétien*, which is very large; the flesh is tender and breaking, and is very full of a rich sugared juice. It is in eating from the end of March till June.

The *La Pastorelle*, which is tender and buttery, and the juice sweet. It is in eating in March.

The *St. Martial*, or the *Angelic Pear*, which has the flesh tender and buttery, and the juice very sweet. It is in eating in March.

The *Wilding of Chaumontelle*, which is melting, the juice very rich, and a little perfumed. It is in eating in January.

The *Brown St. Germain*, which is a very fine high-flavoured pear on dwarfs and standards, and comes in after the *Wall St. Germain*. It continues in eating from December to the end of March.

The *Pear d'Auch*, which was introduced by the late Duke of Northumberland. It much resembles the *Colmar*, but is fuller towards the stalk. It is in eating from Christmas to April, and is, without exception, the best of all the *Winter Pears*.

The *Swan's Egg*, which is a middle-sized pear, in shape like an egg; it is of a green colour, thinly covered with brown; the flesh is melting, and full of a pleasant musky juice. It comes in eating in November. It is healthy, and bears well either as a standard or in any other way.

The *Bergamot de Pasque*, which has also the following names:—the *Terling*, the *Amoselle*, the *Paddington*, and the *Tarquin*. It is a fine handsome fruit, green when gathered, and of a yellowish or straw colour when ripe. It comes into eating about the month of April, continues till June, and makes a very handsome appearance at table.

The *Golden Beurré*, which is a very fine pear; it is of a beautiful scarlet colour next the sun, and of a gold colour on the other side. The

flesh is melting, and the juice high-flavoured. It ripens in October. It succeeds best on an east aspect, and a loamy soil. It is a plentiful bearer. Mr. Forsyth observes, that it "was introduced from Burgundy by the late Marshal Conway, and was first raised, in this country, at his seat of Park Place, near Henley-upon-Thames, now the seat of Lord Malmesbury."

The Williams's Seedling Pear, which resembles a Summer Bonchrétien, but is more juicy, is a great bearer, and ripens in September. Mr. Forsyth says that it "will be a valuable acquisition to the market-gardeners, as it immediately succeeds the Windsor Pear."

The Citron de Carmes, which is a middle-sized pear, of a yellowish-green cast, full at the eye; of a round shape, but tapering a little toward the stalk, which is long. It becomes ripe in July.

And the True Golden Beurré, which in shape and size resembles the Brown Beurré; but is of a reddish-brown colour next the sun. It is a very fine pear, but does not keep long. It comes into eating in October.

Mr. Forsyth gives the following selection from Anderson's and Co.'s Catalogue, of Edinburgh:

Of the Summer Kinds—The Pear James, which is soon ripe, and soon rotten, has a little flavour, and is the earliest pear in Scotland.

The Early Carnock, which is indifferent, of a yellow colour, and bright red towards the sun; making a beautiful standard tree.

The Lemon, Lady's Lemon, or Lady Lamont, which is indifferently good, but principally valued for coming early, and being a good bearer in common.

The Green Pear of Pinkey, which is a small green pear, nearly round, of a sweetish taste or flavour.

The Forrow Cow, a Clydesdale pear, which is a large pear with a short stalk; flat towards the eye; the colour red and yellow; the flesh tender, and musked in its flavour.

The Pear Sauch, a Clydesdale pear, which is a big-bellied beautiful pear; the tree large, a great bearer, and fit for an orchard; but the fruit is not very good.

The Gray Honey, which is a pretty good pear.

The Green Orange Pear, or Orange Vert, which is a very good pear.

The Brute Bone, Chaw Good, or the Pope's Pear, which is only an indifferent sort.

The Golden Knap, supposed Scotch, which is a small Summer Pear, of tolerably good qualities.

The Early Achan, an indifferent fruit; greatly inferior to the Winter Pear of that name.

The Hanging Leaf, which is the name in Clydesdale, is good and beautiful; almost round; its colour red and yellow: a delicious sweetness is found in its taste.

The Scots Bergamot, which is a large good pear, of a yellow and red colour; the flesh tender and juicy.

The Longueville, which is very good, but a precarious bearer; supposed French, though not in their catalogues under that name.

The Muskéd Bonchrétien, Gratioli, Cucumber, or Spinola's Pear, which is a very good pear when grafted on a free stock; its pulp being somewhat between short and tender, with a great deal of perfumed juice; its colour red on one side, and white on the other.

And the Saffron Pear, which is a pretty large well-shaped pear, fit for the orchard or the field.

Of the Autumnal Kinds—The Keather, which is a Clydesdale pear, of middling size, and oblong shape, its juice agreeable.

The French Carnock, which is tolerably good.

The Elshin Haft, or Good-Man Pear, which is a long pear, flat towards the eye; its colour green and yellow; its flesh hard, dry, and sweet in the taste.

The Drummond, or Late Scotch Carnock, which is very good, if eaten before it grows mealy; its colour a bright red and yellow.

The Vicar, an oblong pear, with the colour yellow, red and striped; tender, sweet, and musked, but dry in eating.

The Royal Orange Bergamot, which differs from the Orange Bergamot in being yellower, and sometimes having a faint red on one side.

The Green Pear of Yair, which is sweet, juicy, and melting; of a moderate size; taking its name from Yair, on Tweed-side, where it was first discovered.

The Rob Hind, which is very indifferent.

The Le Besideri, the Wilding of the forest of Ileri in Bretagne, which is a yellowish pear, of middle size, but which is indifferent.

The Unicorn Pear, which is of a beautiful red and yellow colour; but rather austere in the taste or flavour.

Of the Winter Kinds—The Winter Achan, which is a Scotch Pear; among the best early Winter Pears, and equal to most of those of the French kind.

The Brier Bush, which is Scotch; a good pear, and will ripen in most seasons; it is a small pear, of a firm substance, and sweet taste.

The Brompton Park, which is a seedling sent by Jefferys of that name.

The Round Winter, which is a Clydesdale pear; a very excellent Winter Pear.

The Poir Portrail, or Gate Pear, which is proper for baking.

The La Double Fleur, or the Double-flowering Pear, which is a large flat beautiful pear, with a smooth skin, and blush colour on one side, and yellow on the other: it is the best to preserve, taking a beautiful red colour from the fire.

And to these the following list is added:—The Ambrosia Pear, the Ashton Town, the Autumn Musk Bonchrétien, the Bishop's Thumb, the Bloody Pear proper for baking, the Brocas Bergamot, the Barland proper for perry, the Besideri fit for baking, the Beurré du Roi, the Black Pear of Worcester fit for baking, the Britannia, the Burdelieu, the Doyenne or St. Michael, the Catillac fit for baking, the Easter St. Germain, the Gansel's Bergamot, the Golden Beurré, the Gray Beurré, the Gray Goodwife, the Green Sugar, the Green Bergamot, the Huntingdon Pear, the Hufcap proper for perry, the King's Catharine, the Lammias, the London Sugar, the Muscat Almain, the Musk Blanquet, the Oldfield proper for perry, the Orange Bergamot, the Pear Piper, the Pyrus Pollveria, the Red Admirable, the Rough Cap proper for perry, the Scotch Bergamot, the Seven-angled, the Silver-striped, the Spanish Red Warden best for baking, the Squash proper for perry, the Striped Verte Longue, and the White Beurré.

And for small gardens, where there is room only for a few trees, the following are recommended as proper for furnishing a regular succession of fruit:

Summer Kinds—The Musk Pear, the Green Chissel, the Jargonelle, the Summer Bergamot, and the Summer Bonchrétien.

Of the Autumn Kinds—The Orange Bergamot, the Autumn Bergamot, the Gansel's Bergamot, the Brown Beurré, the Doyenne or St. Michael, and the Swan's Egg.

Of the Winter Kinds—The Crasane, the Chaumontelle, the St. Germain, the Colmar, the D'Auch, the L'Eschasserie, the Winter Bonchrétien, and the Bergamot de Pasque.
